This review, emphasizes interventions geared towards younger preschool and school-aged children (as opposed to adolescents) because of the emerging evidence that children who begin antisocial behavior early are at significantly greater risk than those who become antisocial later, both for chronic offending during adolescence and for careers as antisocial adults (Patterson et al., 1989). The following discussion highlights several PT programs which were selected on the basis of their widespread availability, detailed descriptions of training procedures, and extensive evaluation of both the short-term and long-term effectiveness of the intervention.

The most highly influential PT program was developed by Patterson, Reid, and their colleagues at the Oregon Social Learning Center (Patterson et al., 1982; Patterson, Reid, Jones, & Conger, 1975). Spanning two decades of research with more than 200 families, their work provides an exemplary model for outcome research with conduct-problem children. Although directed toward parents of preadolescent and adolescent children who were engaged in overt conduct disorders, their program will be described here because it has provided the foundation for numerous other PT programs.

The program starts with having parents read a programmed text, either *Living with children* (Patterson, 1976) or *Families* (Patterson, 1975). Afterwards, they complete a test on the reading material. The therapist then works with each parent individually in a step-by-step approach wherein each newly learned skill forms the foundation for the next new skill. Five behavior management practices form the core content of the program. First, parents are taught to pinpoint the problem behaviors of concern and to track them at home (e.g., compliance versus noncompliance). Second, they are taught how to use social and tangible reinforcement techniques (e.g., praise, point systems, privileges, treats) and to shift from tangible to social reinforcers over time. Third, they are taught discipline procedures: 5-minute time-outs, short-term privilege removal, response cost, and work chores. Fourth, they are taught to "monitor'—that is, to provide close supervision for their children even when the children are away from home. This involves parents knowing where their children are at all times, what they are doing, and when they will be home. In the final phase of treatment, parents are taught problem-solving and negotiation strategies and become increasingly responsible for designing their own programs. The treatment content has been described in a manual by Patterson (1975) and elaborated upon by Reid (1987).

Like all PT programs, this intervention is based on a model which posits the primacy of ineffective parenting skills in the development of conduct problems: parents inadvertently teach their children noncompliance and aggression by modeling and reinforcing those behaviors in their daily interactions with their children. Here, the focus of intervention is the particular parent behaviors which support the child's negative behaviors. For example, instead of backing down (and rewarding) their child's coercive response to commands, or using harsh punitive parenting to gain compliance, parents are taught to follow through with commands in a reasonable and consistent manner. Instead of ignoring prosocial efforts and attending to negative behaviors, they are taught to reward appropriate behavior that they had hitherto overlooked.

Another influential PT program was developed originally by Hanf (1970) at the University of Oregon Medical School and later modified and evaluated extensively by McMahon and Forehand (1984). It was designed to treat noncompliance in young children, ages 3–8 years. As described by Forehand and McMahon (1981) in their book, *Helping the noncompliant child,* the first phase of this comprehensive PT program involves teaching parents how to play with their children in a nondirective way and how to identify and reward children's prosocial behaviors through praise and attention. The objective is for parents to learn to break the coercive cycle by increasing their social rewards and attention for positive behaviors and reducing their commands, questions, and criticisms. Parents also learn to use social and tangible rewards for child compliance and to ignore inappropriate behaviors. The second phase of the program involves teaching parents how to give direct commands in such a way as to gain more compliance and how to use 3-minute time-outs for noncompliance. Progression to each new skill in the treatment program is contingent on the parent's achieving an acceptable degree of competence in the previously presented skill.

The program is conducted in a clinic setting where the therapist works with individual parents and children together. Treatment methods include role-playing, modeling, and coaching. The clinic utilizes a playroom equipped with one-way mirrors for observation and "bug-in-the-ear" devices through which the therapist can prompt and give feedback to parents while they play with their child. Homework is assigned in the form of daily 10-minute play sessions with the child using the strategies learned in the clinic.

In this intervention the focus is on the reinforcement value of parental attention. Parents are taught to use "descriptive commenting" with appropriate behaviors—that is, to describe their children's behavior when they are acting in appropriate, positive ways—and to praise those behaviors. Parental attention reinforces and thus promotes the replacement behaviors, the positive behaviors which serve to replace the negative behaviors. Only after mastering the use of positive attention are parents taught discipline techniques to limit negative behavior. Reorienting the pattern of parent–child interactions from negative to positive reinforcement is presumed to interrupt the overlearned negative cycles in which many parents of noncompliant children find themselves, and which only promote further noncompliance.

The emphasis of this parent training (Hanf, 1970) on the relational aspects is also found in the intervention developed by Eyberg (1988) called "parent–child interaction therapy" (Hembree-Kigin & McNeil, 1995). While the emphasis on behavior management is maintained, the skills for child-directed play are elaborated in great detail, composed of "DRIP skills": describe, reflect, imitate, praise. Eyberg (1988) presents this program as an integration of traditional play skill values and current behavioral thinking about child management (Eyberg & Boggs, 1989). It is felt that parents' nondirective play with their children improves children's frustration tolerance, helps reduce the anger level of oppositional children, and offers more opportunities for prosocial behavior to occur (Hembree-Kigin & McNeil, 1995). Moreover, engaging in play with their children helps parents recognize their children's positive qualities. As parents learn nondirective play skills, they learn how to respond in a sensitive and genuine manner, how to relate to their child's level of development, and how to stimulate their learning. The primary goal of this training is to strengthen attachment and establish a warm, loving relationship between the parent and child.

Another example of a PT program for young children with conduct problems was developed by Webster-Stratton (1981b, 1982a, 1982b, 1984). Based on the early theoretical work of Patterson (1975) and Hanf (1970) regarding key parenting and relationship skills and behavioral principles to be learned in order to reduce conduct problems, the program utilizes videotape modeling methods. The content of the BASIC program incorporates Patterson's (1982) nonviolent discipline components concerning time-out, logical and natural consequences, and monitoring, components of Hanf's (1970) "child-directed play" approaches and the strategic use of differential-attention, encouragement and praise, and effective use of commands. This content has been embedded in a relational framework including parent group support, mutual problem-solving, self-management, and a collaborative relationship with the therapist. This approach is designed to promote parental self-efficacy and engagement with the program and to reduce parental resistance and drop-out (Webster-Stratton & Hancock, in press). Parents are taught to examine and alter the irrational thinking which derails their implementation of effective parenting. The ADVANCE PT program includes content on problem-solving, communication (D'Zurilla & Nezu, 1982; Spivak, Platt, & Shure, 1976), and self-control techniques. In 1990, another new program was developed, entitled *Supporting your child's education*, to address risk factors related to children's poor academic readiness and weak home/school connection (Webster-Stratton, 1992b). In this program, parents learn how to prepare their preschool children so they can be successful in school. (Webster-Stratton and colleagues have developed a videotape program for teachers based on the same principles; teachers are trained in strategies for managing classroom behavior and for working collaboratively with parents.)

This program of research has been concerned with methods of presenting the parenting program—that is, developing the most cost-effective, widely applicable, and sustaining methods for training parents. Based on Bandura's (1982) modeling theory, the program utilizes videotape-modeling methods. The series of 10 videotape programs of modeled parenting skills (250 vignettes, each of which lasts approximately 1–2 minutes) are shown by a therapist to groups of parents (8–12 parents per group) in 13 sessions (26 hours). The vignettes show parent models in natural situations (unrehearsed) with their children "doing it right" and "doing it wrong" in order to demystify the notion that there is "perfect parenting" and to illustrate how one can learn from one's mistakes. After each vignette, the therapist leads a group discussion of the relevant interactions and encourages parents' ideas. Vignettes of parenting mistakes provide a wonderful opportunity to engage parents in analyses and critical thinking about what makes one technique effective while another is not. Group discussion provides a way for parents to gain acknowledgment for their thoughts and experiences. It also provides a safe forum for disclosure of past mistakes as well as fears, regrets, misgivings, etc. Therapists have the opportunity to model positive self-talk as they discuss vignettes or relate similar experiences, and such talk encourages parents to refrain from self-blame about their own parenting mistakes, and instead to believe in their future successes. Efforts are made to promote the modeling effects for parents by encouraging identification with the models shown on the videotapes; the videotapes show parents of differing sexes, ages, cultures, socioeconomic backgrounds, and temperaments demonstrating different levels of parenting skill, so that parents will perceive the models as similar to themselves and their children. Home activities are given out each week which include daily practice exercises as well as a weekly chapter to read or listen to on audiotape from the book, *The incredible years: A trouble-shooting guide for parents* (Webster-Stratton, 1992a).

The group discussion and collaborative format were chosen to ensure that the intervention would be sensitive to individual cultural differences and personal values, as well as to enhance parents' commitment to parental self-management. The program is also designed to help parents understand and learn to accept normal variation in children's developmental abilities, emotional reactions, and temperament style. The self-management aspect of the program is emphasized by asking each parent to identify the particular positive behaviors they want to see more of in their children and the negative behaviors they want to decrease. These targeted behaviors then become the focus for them to apply the "parenting principles" which they learn in the program. In this sense the program is "tailored" to each family's individual needs and goals as well as to each child's abilities.

The program utilizes group process not only because it is more cost effective but also because it addresses an important family risk factor—namely, the family's sense of isolation and stigmatization. The parent groups enhance and promote parent support networks and mutual collaboration (Webster-Stratton & Herbert, 1993, 1994). This support is also extended during the week by means of weekly assignments which include "buddy calls," a process whereby parents call each other to share their experiences regarding the assignments. However, the program has also been given to over 80 parents of conduct problem children as a completely self-administered intervention—that is, parents view the videotapes and complete the homework assignments without therapist feedback or group support.

5.08.4 RESEARCH FINDINGS REGARDING TRADITIONAL PARENT TRAINING

5.08.4.1 Short- and Long-term Follow-up and Program Generalizeability

The use of PT as an intervention for child conduct problems has been extensively researched, and there are a number of excellent reviews (Henggler, Borduin, & Mann, 1993; Kazdin, 1987; Miller & Prinz, 1990; Patterson, Dishion, & Chamberlain, 1993). Programs have reported high parental ratings of acceptability and consumer satisfaction (Cross Calvert & McMahon, 1987; McMahon & Forehand, 1984; Webster-Stratton, 1989). The success of short-term treatment outcome has been verified by significant changes in parents' and children's behavior and in parental perceptions of child adjustment (Kazdin, 1985; McMahon & Forehand, 1984; Patterson & Reid, 1973; Webster-Stratton, 1981a, 1982a, 1984, 1990a; Webster-Stratton, Hollinsworth, & Kolpacoff, 1989) in comparison to waiting-list control families. Home observations have indicated that parents who have undergone training have been successful in reducing children's levels of aggression by 20–60% (Patterson et al., 1982; Webster-Stratton, 1985b). While the majority of studies have been conducted with Caucasian mothers, there is some evidence that parent training is also effective with fathers (Webster-Stratton, 1985a, 1990a) and with ethnic minorities (Strayhorn & Weidman, 1989; Webster-Stratton, 1995).

Generalization of behavior improvements has been demonstrated from the clinic setting to the home (Patterson & Fleischman, 1979; Peed, Roberts, & Forehand, 1977; Webster-Stratton, 1984) over reasonable follow-up periods (1–4 years) and to untreated child behaviors (Arnold, Levine, & Patterson, 1975; Fleischman, 1981; Forehand & Long, 1986; Webster-Stratton, 1982a; Webster-Stratton & Hammond, 1990). A 14 year follow-up of parents who attended the Forehand and McMahon program indicated that treated families were performing comparably to non-referred "normative" samples on measures of internalizing and externalizing behaviors, social competence, relationship with parents and academic progress. Unfortunately, the data are mixed regarding generalization of child behavior improvements from the home to the school setting.

Several studies have found that even when a child's behavior improved at home, his or her teacher did not necessarily report improvements in conduct problems and peer relationships in the classroom (Breiner & Forehand, 1982; Forehand, Breiner, McMahon, & Davies, 1981; Forehand, Rogers, McMahon, Wells, & Griest, 1981; Forehand et al., 1979). The Webster-Stratton (1981a) program found significant improvements in child adjustment at school as reported by teachers immediately post-treatment, but a year later these were not maintained. In another randomized study of 43 aggressive boys (grades 2–6), when treatment families were compared with a waiting-list control group, they showed significant increases in family cohesion, empathy, problem-solving efficiency, total family relationships, and positive child behaviors at home and school, with corresponding decreases in family conflict and negative/aggressive child behaviors at home and at school (Sayger, Horne, Walker, & Passmore, 1988). In a follow-up study of this sample, Sayger, Horne, and Glaser (1993) found that these positive changes in behavior at school, in marital satisfaction, in maternal depression, and in family relationships in general were maintained.

5.08.4.2 Comparison of PT with Other Types of Family Therapy

A few studies have compared the basic PT approach with other forms of family therapy. Patterson compared families randomly assigned to his PT program with those who received treatment from various clinicians in the community representing a range of therapeutic approaches. Results indicated the superiority of PT in producing reductions in child deviance (Patterson et al., 1982). In a subsequent study, Patterson and Chamberlain (1988) randomly assigned parents to their PT program or to a community agency employing eclectic family therapy. Findings indicated significant reductions in child deviant behaviors for PT, but no significant reductions for children in the family therapy condition. Wells and Egan (1988) also evaluated a study comparing PT with family systems therapy. Results indicated that their program was more effective than family systems therapy based on observations of parent and child behaviors, but both programs showed significant decreases in child problem behaviors as reported by parents.

In 1996, Taylor, Schmidt, and Hodgins (1996) reported on a study where they randomly assigned 110 families to a waiting-list control group, to Webster-Stratton's PT program (videotape modeling therapist-led group approach), or to a children's mental health center whose usual treatment approach to conduct problems was eclective, based on individual intervention tailored according to the therapist's personal assessment of a family's needs. Results indicated that the PT program was superior to eclectic treatment in terms of mother's reports of child improvements at home, mothers' confidence levels, and overall consumer satisfaction.

In addition to comparing PT with other forms of family therapy, there have been some attempts to determine which aspects of PT account for the improvements resulting from treatment. For example, to what extent is therapeutic change accounted for by the content, the therapy methods (i.e., videotape modeling), the group support, or the therapist's interpersonal skills? In this vein, Webster-Stratton and colleagues have attempted to determine which methods of PT are most effective. In their first randomized study, they showed that the therapist-led group discussion videotape modeling method (GDVM) was equally good if not more effective than a PT method based on the highly individualized one-to-one "bug-in-the-ear" approach involving direct coaching of the parent and child (Webster-Stratton, 1984). Next they showed that PT based on the GDVM approach was somewhat more effective than either PT based on a therapist-led group discussion approach—without videotape modeling (GD)—or a completely self-administered videotape modeling approach—without therapist feedback or group discussion (IVM) (Webster-Stratton et al., 1988, 1989). All three approaches showed significant improvements in comparison to the waiting-list control condition—even the self-administered videotape modeling program had better treatment adherence than the group discussion approach without videotape modeling. At 3 year follow-up, the improvements in conduct problems (as reported by parents) were maintained only in the group trained by GDVM. In contrast, parents in both the IVM and GD conditions reported significant increases in their children's conduct problems from the 1 year to 3 year follow-up (although still below baseline levels). This component analysis of PT methods seems to suggest that PT methods based on videotape modeling plus parent group discussion and support will produce more sustained and long-term effects than programs which do not use videotape modeling or group discussion and mutual support methods. Moreover, the group approach represents a cost-effective alternative to conventional family therapy (i.e., individual therapy with a single family).

5.08.4.3 Factors Contributing to Program Success or Failure

Despite the general overall success of these programs in producing statistically significant changes in parent and child behaviors, there is also evidence that some families do not respond to treatment; these children continue to have clinically significant behavior problems after treatment (Eyberg & Johnson, 1974). In long-term follow-up studies, 30–40% of treated parents and 25% of teachers report children to have behavior problems in the deviant or clinical range (Forehand, Furey, & McMahon, 1984; Schmaling & Jacobson, 1987; Webster-Stratton, 1990a; Webster-Stratton & Hammond, 1990). In the Forehand and Long (1986) review, according to behavior observation measures, 4 of the 12 programs failed to produce changes in behavior that were maintained over time; and follow-ups were beset with high attrition rates (50%). In an effort to account for these treatment failures, researchers have focused on identifying variables other than parenting skills which may be directly or indirectly related to the continuation of conduct problems. In particular, there is an emerging literature concerned with family variables such as parents' personal problems, marital relationships, and relationships with others outside the family. Parent and family characteristics such as parental depression, marital conflict, spouse abuse, lack of a supportive partner, poor problem-solving skills, and high life stress have been shown to be associated with fewer treatment gains (Forehand et al., 1984; Forgatch, 1989; Webster-Stratton, 1985b).

5.08.4.3.1 Parental depression

There are somewhat conflicting results regarding the influence of depression on parents' ability to benefit from PT (Forehand et al., 1984; Wahler, 1980; Webster-Stratton, 1988; Webster-Stratton & Hammond, 1988). Researchers have long noted that pretreatment levels of maternal depression (self-reported symptoms, not formal diagnosis) are significant predictors of attrition rates during PT (McMahon, Forehand, Griest, & Wells, 1981) and failure to take part in follow-up assessments. However, research has rarely evaluated paternal depression as a predictor of treatment outcome. In the only study to be found concerning the role of fathers' depression, Webster-Stratton and Hammond (1990) evaluated the relative contribution of maternal and paternal depression (along with other variables related to parents' mental and emotional states) to short-term and long-term treatment outcome for 101 families who had been treated for their children's conduct problems via PT. They found that pretreatment levels of maternal and paternal depression (as measured by the Beck Depression Inventory) were significant predictors of maternal and paternal reports of their children's maladjustment (i.e., failure to fall into the normal range on standardized parent report measures) immediately post-treatment; however, reported depression was not related to clinically significant behavioral improvements following treatment—either in parenting behaviors (i.e., a 30% drop in criticisms from baseline) or in the child's interactions with mothers or fathers (i.e., a 30% drop in total negative behaviors from baseline) (Webster-Stratton, 1994). At 1 year follow-up, pretreatment levels of depression still predicted mother and father reports of child adjustment, but again were not related to parent and child behavioral improvements at home (as independently observed) or to child behavior at school (as reported by teachers). On the other hand, marital status and socioeconomic status for mothers were strong predictors of continuation of mothers' critical behaviors and child conduct problems post-treatment, while marital dissatisfaction and negative life events were strong predictors of fathers' critical behaviors and child conduct problems at follow-up. This study confirmed an earlier study by Forehand and Furey (1985) which found an association between marital satisfaction and parent and child behaviors, and an association between depression and mothers' perceptions or attributions concerning their children, but not mothers' behaviors.

Studies have also shown that maternal depression significantly improves following PT when subjects are compared with waiting-list control mothers (Forehand, Wells, & Griest, 1980). In a study involving 85 families of children with conduct problems, Webster-Stratton (1994) reported that both mothers and fathers showed significant reductions in depressive symptoms immediately after PT, levels which were maintained 2 years later. Of the total sample, 31.2% of mothers and 22.4% of fathers indicated depressive symptoms in the mild to moderate range pretreatment; after PT, 54.2% of the depressed mothers and 83.3% of the depressed fathers had changed into the normal range. Further analysis indicated that those mothers who showed significant improvements in their depression scores (into the normal range) reported more significant improvements in child adjustment than mothers whose depression scores remained abnormal, and their children showed a higher ratio of positive to negative social skills (30% increase) than children of mothers with abnormal depression scores. For fathers, no significant relationships were found between an improvement in depression level and improvements in child behavior. These data suggest that the best predictor of long-term treatment outcome for children may be mothers' post-treatment levels of depression, rather than pretreatment levels.

5.08.4.3.2 Marital conflict

Next, consider the impact of marital conflict on treatment outcome (Grych & Fincham, 1990). Earlier it was noted that the relationship between the intensity of marital conflict and levels of childhood behavior problems (Fantuzzo et al., 1991). Unfortunately, only a few studies have examined the relationship of marital variables to treatment outcome for parents of children with conduct disorders. Some of the early studies (Oltmanns et al., 1977) found no relationship between pretreatment levels of marital adjustment and treatment outcome, and found no changes in marital satisfaction following treatment. However, others have found marital distress to be an important predictor of treatment failure (Dadds et al., 1987; Webster-Stratton, 1994). Dadds found that marital conflict was predictive of poor treatment outcome assessed at 6 month follow-up (Dadds & McHugh, 1992). In Webster-Stratton and Hammond's (1990) study, marital status and marital conflict (for mothers and fathers, respectively) were factors that made the greatest contribution to the prediction of child behavior problems immediately post-treatment. One year later, marital status was the strongest predictor of treatment outcome as measured by teachers' reports of child behavior; single-parent families accounted for significantly more nonresponders to treatment (Webster-Stratton, 1990a). Mothers of children classified as nonresponders also reported significantly lower income and more depression than mothers of children classified as responders. However, at 1 year follow-up there were no significant differences in levels of marital conflict reported by parents of children classified as responders and parents of nonresponders. Moreover, Webster-Stratton found that marital conflict did not improve as a result of PT, unlike mothers' depression. Consequently, it appears that while PT can improve parent–child interactions and maternal depression, it has no impact on marital satisfaction or conflict; conversely, marital conflict and marital satisfaction do appear to have an impact on the outcome of PT.

These findings suggest a model in which the key causal factor behind child conduct problems is not lack of parenting skills *per se*, but rather parents' lack of conflict management skills. Parents who have more difficulties with communication, conflict resolution, and affect regulation find it harder to cope with life stressors, marital disagreements, and common child misbehaviors. As a result, not only do they fall into the negative reinforcement trap when parenting, but they also model their troubled communication and affective patterns for their children, thereby further contributing to their children's difficulties with peer relationships including poor communication and poor problem-solving, as well as escalating anger and aggression.

5.08.4.3.3 Insularity and socioeconomic disadvantage

How do insularity, family socioeconomic disadvantage, and high levels of life stress contribute to treatment success or failure? Recruitment rates for PT interventions with low-income families of conduct-disordered children are low (Spoth & Redmond, 1995). Families who are socioeconomically disadvantaged have often been reported to be more likely to drop out of treatment (Eyberg, 1992) and more likely to relapse or fail to make clinically significant improvements following treatment or to maintain treatment effects over time (Dumas & Wahler, 1983; Wahler & Afton, 1980; Wahler & Dumas, 1984; Wahler & Fox, 1982; Webster-Stratton, 1985b). In a study of 257 clinic children and their families who initiated treatment for aggressive behavior, it was shown that parental stress (total stress and life events) predicted early drop-out from treatment but not late drop-out (Kazdin & Mazurick, 1994). Wahler (1980) found that mothers who reported having had negative interactions with their community before treatment were less likely to maintain treatment effects over time.

Socioeconomic disadvantage coupled with social isolation or insularity resulted in a steady increase in the probability of PT treatment failure (Dumas & Wahler, 1983). Finally, in another study it was shown that those clinic families who had a partner or father involved in treatment (presumably providing more support) were more likely to sustain treatment effects 2–3 years later (Webster-Stratton, 1985a). A family's ability to maintain treatment effects at one year follow-up has been correlated with their degree of negative life crisis and environmental stresses (e.g., move to new neighborhood, death in family, unemployment), degree of insularity or support, and poverty (Webster-Stratton, 1985b).

All of these findings taken together suggest that PT programs need to be broadened to emphasize partner involvement (see earlier discussion regarding marital support and communication training), parent support, marital communication, problem-solving and coping skills. Moreover, the failure of many programs to result in child behavior improvements which generalize to school settings suggests the need for some form of training that equips parents to collaborate with teachers in order to improve their children's behavior at school as well as at home. This broadened view of PT will more accurately reflect the more complex model concerning the etiology of conduct problems.

5.08.4.3.4 Child characteristics

With respect to child characteristics, such as the nature of the child conduct problems, the child's age, sex, race, and particular biology, there is a lack of information concerning the important child predictors of long-term treatment outcome. Outcome studies rarely separate results for preschoolers from results for school-aged children. However, there is a suggestion from several follow-up studies of PT programs for parents of children with conduct disorders that the younger the child at the age of treatment, the more positive the child's behavioral adjustment at home and at school (Strain, Steele, Ellis, & Timm, 1982). Dishion, Patterson, and Kavanagh (1992) reported that children aged 2–6 years had the most significant improvements. Neither sex nor race have predicted outcome, although there is a suggestion in the literature that there may be different etiological factors leading to ODD/CD for girls and boys (Webster-Stratton, 1996a). There is scant research concerning how child biological factors affect PT outcome, although it has been suggested that the prognosis is worse for children with conduct problems combined with ADHD (unless medication is added) (Barkley, 1996; Walker, Lahey, Hynd, & Frame, 1987). Nonetheless, this research was carried out with older children, leaving it unclear how child biological factors influence PT for young children. Webster-Stratton's studies did not find that child age, sex, or hyperactivity predicted treatment success; instead, it was family factors such as life stress, socioeconomic status, and marital conflict that predicted long-term outcome in terms of the continuation of child antisocial behavior following her PT program (Webster-Stratton, 1985b; Webster-Stratton & Hammond, 1990).

5.08.4.3.5 Therapy characteristics

It is clear that not all PT programs are equally effective. Therapy factors, such as the format and methods of training, the dose and length of treatment received, and therapist characteristics, undoubtedly play an important role in predicting treatment outcome. However, these therapy factors have rarely been evaluated. For example, length of treatment has rarely been assessed as an independent variable. Kazdin (1987) has suggested that PT programs less than 10 hours in duration are less likely to be effective with conduct-disordered children. Certainly the programs which we have highlighted above have been lengthy, ranging from 20 to 45 hours. Related to the length of the treatment program is the dose of therapy which the family actually received. There is some suggestion in the literature that families who attend more sessions (greater than 50%) have a more successful outcome than families with poor attendance (Strain et al., 1982). However, this finding has not been reported by other researchers (Dumas & Albin, 1986). Another factor related to treatment dose is whether the father (or some other family member) participated in the training along with the mother. In one study, it was shown that those clinic families who had a partner or father involved in treatment (presumably providing more support) were more likely to sustain treatment effects 2–3 years later (Webster-Stratton, 1985a). The existing evidence would suggest that the involvement of another supportive family member leads to better generalization and maintenance of treatment effects over time (Webster-Stratton, 1985a; Webster-Stratton et al., 1988). Finally, Webster-Stratton's studies suggest that treatment methods such as group support and videotape modeling add substantially to the long-term effectiveness of PT programs (Webster-Stratton, 1984, 1990a).

5.08.4.3.6 Therapist characteristics

There is even less research concerning the role of the therapist and the therapeutic process in predicting treatment outcome. Webster-Stratton and Herbert c(1993, 1994) have described their PT programs as based on a collaborative or partnership model, whereby the therapist works *with* parents by actively soliciting their ideas and jointly involving them in the process of problem-solving, sharing, discussing, and debating ideas and solutions (also see Webster-Stratton & Herbert, 1994). It is suggested that this approach empowers parents by giving back dignity, respect, and self-control to parents who are often seeking help for their children's problems at a vulnerable time of low self-confidence and intense feelings of guilt and self-blame (Spitzer, Webster-Stratton, & Hollinsworth, 1991). On the other hand, some behavioral PT programs seem to be based on an "expert" or hierarchical model, whereby the therapist is more directive—suggesting solutions and dispensing advice for the parents. To this author's knowledge, there has been no research comparing PT programs in terms of their different helping models and different sets of assumptions about the cause of family problems.

While there are no comparison studies, one of the most comprehensive microsocial analyses of therapist–client interchanges was conducted by Patterson and Forgatch (1985). They showed that directive therapist behaviors such as "teach" and "confront" increased the likelihood of parental resistance and noncooperativeness in a session. On the other hand, therapist behaviors such as "facilitate" and "support" led to reliable decreases in client noncompliance. Patterson and Chamberlain (1988) have proposed a therapy model which postulates that therapist behaviors play a secondary role to extrafamilial, interpersonal, and child factors in predicting parent response to the early stages of treatment, but play a primary role in predicting client noncompliance in the later stages of therapy. In another study, Alexander and Parsons (1973) examined the role of therapist characteristics in predicting outcome (as defined by completion of treatment and recidivism rate) for families that participated in family functioning therapy (FFT). They found that relationship characteristics (affect, warmth, humor) accounted for 45% of the variance in predicting outcome, whereas structuring characteristics (directiveness and self-confidence) only accounted for an additional 15% of the variance.

5.08.4.4 Limitations of Studies Related to Treatment Outcome

The research regarding treatment outcome is beset with methodological problems. First, there is a lack of unanimity as to what is meant by "successful" treatment or "improvement" in conduct problems. Different studies have utilized different criteria for evaluating treatment outcome as well as different measures of those criteria. Because of the expense involved in observational methods, some studies have used mothers' reports of improvement in the child's behaviors as the definitive outcome criterion; however, global ratings by parents may reflect how they feel about themselves and their child, rather than any real change in child behavior. Further, it appears that the validity of raters' evaluations varies according to characteristics of the raters. For example, Patterson has shown that the more deviant or socially disadvantaged the parents, the less convergence there is between their ratings and teacher ratings or observational ratings (Patterson et al., 1993). Studies of clinical samples have shown maternal ratings of problem children to be correlated more highly with their self-ratings of depression than with the observed behavior of their children (Forehand et al., 1984; Griest, Forehand, Wells, & McMahon, 1980). Patterson and Narrett (1990) have suggested that mothers' ratings of child behavior reflect improvement even when there is no treatment—resulting in the impression that anything and everything works! On the other hand, neither is independent observation of behavior a wholly unbiased method of evaluating change, though it appears to be less susceptible to some of the problems of self-report measures.

Even when researchers agree on the criterion for evaluating treatment outcome, there may be no agreement on what variable represents that criterion. For instance, if observable behavior is the criterion, the question then becomes whether the relevant outcome variable is parent behavior or child behavior. Whether one expects parent and child behavior to change simultaneously depends on one's theoretical model. Those who ascribe to the PT model believe that changes in parenting behavior (the most proximal variable being influenced by the treatment) eventually will cause changes in child behaviors (the more distal variable), which implies that the appropriate criterion for evaluating the success of PT is, at least for the short term, parenting behavior. Support for this theory is found in one study which showed that the magnitude of changes in parental discipline correlated significantly with changes in antisocial behavior (Dishion et al., 1992). Patterson and Forgatch (1995) examined separately the contributions of baseline, termination, and change scores from parent and teacher reports, as well as observations and process variables to determine their validity as predictors of future child outcomes. The results indicated that termination scores for parents' behaviors post-treatment and the amount of change in parental practices (i.e., positive problem-solving) were powerful predictors of long-term outcome for children, defined as future arrests or removal from home. Neither termination ratings nor change ratings of teacher or parent reports nor termination scores of child adjustment immediately post-treatment predicted future child arrests or out-of-home placements. This study supports the use of parent behavior as predictors of child outcomes—and yet there is no consensus that child arrests or out-of-home placements are criteria for treatment success.

Another issue regarding treatment outcome is: how much change constitutes significant improvement? Often observational measures lack normative data on comparable nonclinic samples with which to compare our clinic samples. As a result, researchers typically utilize percentage improvement from baseline to indicate clinically significant change. But there is no consensus regarding the degree of improvement—the percentage of change—that is necessary to declare behavior "improved." Moreover, in a case where a child does show a 30% or even a 50% reduction in aggressive or noncompliant behaviors from baseline, but is still in the clinical range, is he or she defined as improved or not?

The next limitation to existing research concerns risk factors. As can be seen, in this review, studies typically have analyzed a single risk factor by means of global measures (such as depression, marital satisfaction, family insularity, or life stress) and correlated it with some aspect of treatment outcome. Just as there is a problem with the use of global self-report measures of treatment outcome, there is a problem with the use of global self-report measures as predictors. Global reports do not elucidate the precise aspects of, say marital distress or depression, nor the mechanisms by which these problems maintain the problem behaviors—i.e., contribute to the failure of treatment. In addition to this problem, most studies have been based on short-term results of treatment; they have told us little about the more important concern, namely how these family processes influence long-term treatment outcome. Moreover, very few studies have compared the relative weight or contribution of individual risk factors (such as depression in combination with marital distress) with treatment outcome. In comparison to the large number of individual treatment outcome studies, there is a paucity of studies containing any information about predictors of treatment success, in most cases because the study sample size was too small to form any meaningful conclusions.

Another problem with the research on risk factors is that those studies which have looked at predictors of treatment outcome in terms of children's conduct problems have tended to combine both boys and girls in their samples. It is highly probable that the predictors will be different for boys and girls. Webster-Stratton (1996a) found not only that the predictors differed depending on whether the outcome variable assessed was child externalizing problems at home (according to independent observations) or at school (according to teachers), but also that there were gender differences in predictors: mother negativity and depression and father negativity and life stress significantly predicted girls' externalizing problems 2 years post-treatment and accounted for 49% of the variance, whereas for boys no parenting or family variables emerged as predictors—rather independent observations of externalizing behaviors at baseline were the best predictors of boys' continuing externalizing problems at home 2 years later.

5.08.5 BROADENING THE FOCUS OF PT

Despite the limitations in research studies and differences in outcome measures employed, there has been remarkable consistency in the findings and they seem to hold true even in the face of these problems. Research results regarding the characteristics of families who failed to respond to PT pointed to the necessity of expanding our etiological models as well as broadening our PT focus. Since the mid-1980s, efforts have been made to improve the effectiveness of PT by adding other therapy components to the basic programs: training in social learning principles, problem-solving, self-control and emotional regulation, marital communication, anger management skills, "synthesis training," and ways to give and get support. These components include more sophisticated affective and cognitive skill training. Evaluation of the effectiveness of these adjuncts to PT helps test models regarding the important factors contributing to the maintenance of conduct problems.

5.08.5.1 PT with Marital and Other Parent-focused Adjuncts

Based on the studies indicating associations between marital conflict and poor child-treatment outcomes, a number of investigators have evaluated the effects of adding specific marital treatment components to standard PT. Greist et al. (1982) compared PT with a program which combined PT with a focus on marital adjustment and extrafamilial relationships. The combined program showed greater improvements in terms of child deviance at short-term follow-up. Dadds et al. (1987) examined the specific effects of a brief marital communication intervention, partner-supported training, as an adjunct to PT for parents with a child who had conduct problems. Results indicated that the adjunctive marital component led to enhanced treatment outcomes for couples experiencing discord (but not for maritally satisfied couples) compared with the couples experiencing discord who received only PT (Dadds & McHugh, 1992; Dadds et al., 1987).

Two other consistently documented factors related to treatment failure or drop-out and failure to maintain change following treatment are social disadvantage and isolation (Dumas & Albin, 1986; Webster-Stratton, 1985b). A number of studies have developed PT programs addressing these issues. Wahler (1980) and Wahler and Dumas (1989) defined "insular" parents as those who experience low levels of positively perceived social interactions and high levels of negatively perceived coercive exchanges within the community. They hypothesize that insular mothers have disruptions in their monitoring processes which interfere with their ability to adequately monitor their children and result in indiscriminate responding. Consequently, these researchers developed an adjunct treatment called "synthesis training" whereby parents are taught how their external events or circumstances influence their parenting behavior in order to help them be more effective at monitoring and providing discriminate responses. Synthesis training has been evaluated with multistressed mothers of children with conduct problems (Wahler, Cartor, Fleischman, & Lambert, 1993) and compared with PT alone, and with PT plus friendship liaison. Results indicated that parents who received the synthesis training had reductions in their indiscriminate parenting and their children demonstrated behavioral improvements. Mothers in the basic PT did not change their behavior, nor did their children.

Dadds and McHugh (1992) assessed the role of social support in the outcome of PT for single parents of conduct problem children and assessed the impact of "adjunctive ally support" training (AST) on treatment outcome. Single parents with children diagnosed with ODD or CD were randomly assigned to PT or PT plus AST. Improvements were found in both groups, but AST produced no extra gains. However, responders from both groups were more likely than nonresponders to report high levels of social support from friends, a finding which is consistent with that mentioned earlier regarding father involvement in the PT (Webster-Stratton, 1985a).

In an attempt to address a number of family issues including social support, marital issues and maternal depression, Webster-Stratton (1994) developed a lengthy, 14 week adjunct program (ADVANCE) involving therapist-led group discussions of videotape vignettes on all the following topics: strengthening social support and self-care, personal self-control, family communication skills, problem-solving between adults (and with teachers), and teaching children to problem-solve. Emotional communication is a major emphasis of this advanced program. This is an important skill for families who have until recently felt overwhelmed by negative affect, and who may have indirectly or directly communicated to their children that negative emotions are too frightening or too aversive to share. Parents learn to talk to children about emotion and to respond to their children's emotions appropriately and contingently as a way of increasing their children's emotional regulation (Denham, 1989; Denham, Zoller, & Couchold, 1994).

Families of children with conduct problems were randomly assigned to either the basic PT (GDVM) or GDVM plus ADVANCE. Results immediately post-treatment showed significant improvements in parents' problem-solving, communication and collaboration skills, as well as in children's problem-solving, for families in the combined treatment. Both mothers and fathers from the combined program reported increased consumer satisfaction, and there were no drop-outs from the ADVANCE program, suggesting the perceived usefulness of the skills taught in this program. Moreover, fathers who showed improvements in marital communication and problem-solving post-treatment also showed significantly greater improvements in parenting skills (specifically, reduced hostility and criticisms with children). However, children of ADVANCE parents failed to show significantly enhanced improvements over the children of GDVM parents in terms of child deviance. Both groups of children showed significant reductions in child deviance at home. It was hypothesized that the effects of the ADVANCE parents' improved communication and problem-solving skills may have been delayed, as children need to be exposed to repeated modeling over a sustained period of time. This suggests the need for longer-term follow-up of the two groups.

In summary, studies which have investigated the potential contribution of adjuncts to the standard PT intervention have generally indicated that components which address the social context of families, marital issues, and parental depression can improve the short- and long-term outcomes over and above basic PT (Dadds et al., 1987; Griest et al., 1982; Webster-Stratton, 1994 1997b).

5.08.5.2 PT with Child Training Adjuncts

Studies have indicated that children with ODD/CD may have some sociocognitive deficits in social problem-solving, self-control, and perceptions; these may be of biological origin, may be the result of parental modeling, or some combination of the two. This has led to a few studies evaluating the effects of combining child training (CT) with PT. Kazdin, Siegel, and Bass (1992) compared three interventions: PT, problem-solving skills training for children (PSST), and PT combined with PSST. Each treatment reduced overall child conduct problems and increased social competence. However, the combined treatment led to more durable changes in child behavior, placing a higher proportion of children in the range of normal functioning. The combined treatment also resulted in greater changes in parent functioning, including reductions in parental stress, depression, and overall symptoms. These results were maintained at 1 year follow-up. In another study, Baum, Reyna-McGlone and Ollendick (1986) compared three different interventions: PT, PT combined with child self-control training, and a control condition in which parent discussion was combined with a child attention control condition (control). Results indicated that the PT intervention (with or without the CT component) was superior to the control condition and, for the most part, the two treatment conditions did not differ from each other immediately post-treatment. However, at follow-up the combined treatment (PT plus child self-control training) was superior to PT alone and to the control condition on observational measures of child deviant behavior and on child and mother reports of adjustment.

Finally, Webster-Stratton (1997b) compared four conditions: PT, CT, CT + PT, and a waiting-list control group. Post-treatment assessments indicated that all three treatment conditions had resulted in significant improvements in comparison with controls, as measured by mother and father reports, daily observations of targeted behaviors at home and laboratory observations of interactions with a best friend. Comparisons of the three treatment conditions indicated that CT and CT + PT children showed significant improvements in problem solving as well as conflict management skills, as measured by observations of their interactions with a best friend; differences among treatment conditions on these measures consistently favored the CT condition over the PT condition. As for parent and child behavior at home, PT and CT + PT parents and children had significantly more positive interactions in comparison with CT parents and children. One year follow-up assessments indicated that all the significant changes noted immediately post-treatment were maintained over time. Moreover, child conduct problems at home had significantly lessened over time. Analyses of the clinical significance of the results suggested that the combined CT + PT condition produced the most significant improvements in child behavior at 1 year follow-up.

In summary, these studies on child adjuncts to PT support the hypothesis that supplementing PT with a component that addresses the child directly increases the efficacy of PT. Additionally, these data point to the necessity for long-term assessment of interventions, since the benefits of the adjunct treatment often were not evident until the follow-up evaluation.

5.08.5.3 Future Directions for Research and for Practice

Our review of the research regarding PT has focused on programs for children with ODD/CD because this area comprises the largest body of research regarding PT. Second, we have focused on programs that target preschool and school-age children rather than adolescents because we feel adolescent conduct disorders necessitate other interventions such as individual therapy in addition to or alongside PT. We have not reviewed PT programs specifically targeted at other childhood disorders such as autism, anxiety disorders, learning disabilities, and ADHD.

Despite the limitations of existing research, the evidence appears to support a more comprehensive, multisystem-based model in which conduct problems are not seen merely as evidence of inept parenting skills which need to be changed via treatment, but instead where parenting behavior is seen to be impacted by the events and conditions within and outside the family. We believe the findings to date argue for broader-based treatments which address multiple risk factors and strengthen multiple protective factors such as parenting skills, support networks, and problem-solving and communication as a means of preventing early-onset conduct problems. By strengthening parenting skills and problem-solving strategies and ensuring adequate support (through broader-based family training support groups) for families of young children with conduct problems, we can help families buffer some of the potentially disruptive effects of ongoing depression, marital conflict, negative life stress, and poverty on children's adjustment. Indeed, initial studies of broader-based interventions suggest they promote more enduring child improvements which generalize across settings and over time, as well as fewer treatment drop-outs. Combining PT with CT appears to lead to even greater maintenance of improvements in parent and child behaviors.

Nonetheless, the original formulation of Patterson et al. (1975) is still compelling, particularly as it relates to young children with conduct problems: parenting skills are the most important proximal cause of early-onset conduct problems, because parents are still the primary agents of socialization of the child at this age. Given that this formulation is correct, the success of treatment programs in changing the parenting behavior of parents of young children should predict the child's future adjustment. For children aged 3–7 years, peer rejection, deviant peer groups, academic failure, and negative reputations have not stabilized, whereas for the older school-age child these factors play a key role in maintaining the conduct problems and must be taken into account in intervention. Moreover, parents of younger children are still hopeful and their patterns of parenting are more malleable than those parents who have spent years of coping unsuccessfully with an oppositional child at home. Support for this idea comes from studies which have suggested that PT is more effective in improving both parenting skills and child adjustment when offered to parents of younger children versus older school-age children and adolescents (where presumably more will be required in terms of direct intervention with the child and his or her peer group) (Strain et al., 1982). Further support for the importance of developing comprehensive interventions that can strengthen parenting skills and thereby influence the long-term outcome for children's adjustment is provided by Patterson and Forgatch's (1995) study.

5.08.5.4 Expansion Across Multiple Settings

Nonetheless, while PT holds much promise for treating children with conduct problems, there are several important limitations to this approach. The first important limitation is the inability of this approach to consistently produce child behavior improvements which generalize beyond the home to day-care or school settings and to peer relationships. While the majority of children improve their social behavior at home, 30–50% continue to have significant school problems such as social acceptance, conduct problems, and academic underachievement. Intervening with children's teachers as well as their parents would seem to offer far better possibilities of generalizing improved social skills from the home to preschool and school settings. In particular, schools may enhance the effects of PT by providing teachers not only with classroom behavior management training, but also with the curriculum and support to directly offer training in social skills and problem-solving.

A second limitation is that, despite the documented links between academic underachievement, language delays, reading and learning disabilities, ADHD, and conduct disorders, PT programs rarely, if ever, have included an academic skills enhancement program for parents. Parents need to know not only how to help their children with their antisocial problems but also how to teach and support them regarding their academic difficulties. They need to know how to work with teachers and schools in order to foster a supportive relationship between the home and school settings. Parents and teachers alike need to understand how to collaborate with one another, to build supportive teams to help these children both academically and socially. Such a coordinated effort between the home and school regarding social and academic goals will offer the possibility for more consistent generalization of child improvements across settings. There is little or no research comparing PT with PT offered in conjunction with teacher training or, more generally, evaluation of intervention efforts to span home and school. Research which evaluates the added effects of combining teacher training and parents' academic skills training to our traditional PT approaches should be encouraged.

5.08.5.5 Teachers and Other Professionals

Since preschoolers living in more dysfunctional or disrupted family environments or in poverty are at particular risk for persistent problems, the need for strong educational and therapeutic preschool programs with nurturing and well-qualified teachers is critical. This means preschool teachers and child care workers should be well trained in child development and behavior management skills. Stable and nurturing caregivers may be able to buffer the effects of parental unavailability or psychopathology, at least for some children. However, all too often these are the very children who are spending large amounts of time in the least adequate facilities with untrained caregivers, where child-to-caretaker ratios make it impossible to provide the attention, affection, and emotional support they need. Finally, since parents bring their first questions about common developmental issues and problem behaviors to their pediatrician or family physician, these professionals also need training that allows them to understand parental perspectives within a developmental framework—so that they neither pathologize common problems nor minimize parents' concerns.

5.08.5.6 Addressing Extrafamilial Change

Interventions which have focused on adjuncts to PT reflect a paradigm shift from individual change (i.e., parenting skills) to within-family change (i.e., marital communication and problem-solving skills). But there has been no further shift to what might be called extrafamilial or interfamilial change, such as a family's need to form stronger and more supportive connections with other families and with the community in general. We theorize that, particularly for low-income families, there is an urgent need to broaden PT programs so as to focus on building community and parent support networks. Indeed there is evidence from the "buffering" interpretation of social support (Cohen & Willis, 1985) that particularly for low-income families, the greater the number of people parents felt they could rely on for informal assistance and the more satisfied they felt with their social support, the more likely they were to be nurturing and positive in their parenting interactions and the less likely they were to report problematic behavior (Hashima & Amato, 1994) compared with low-income mothers who felt isolated and dissatisfied with their social support (Jennings, Stagg, & Conners, 1991).

Many interventions have been based on the individual one-to-one counseling model which fosters reliance on the therapist. Those programs which have used a group approach (Webster-Stratton, 1994) have suggested that fostering supportive social networks was a primary purpose of the group approach. The therapeutic group can decrease families' isolation, promote a feeling of support and involvement, and build a sense of community. However, little reference is made to the specific therapeutic strategies used to achieve this goal. Indeed, compared with our well-developed research methods of measuring parent behavior change, few studies report outcome measures having to do with change in social networks, parents' sense of support, or their involvement in their communities (including their children's school) as a result of PT. If we are going to develop more effective interventions targeting these factors, we will need suitable outcome measures (Webster-Stratton, 1997a).

5.08.5.7 Engaging Low-income Families, Understanding Obstacles and the Importance of Culture

The PT literature has suggested that PT is less effective with disadvantaged parents—particularly low-income single mothers (Wahler, 1980). Such families have been described as unmotivated, resistant, unreliable, disengaged, chaotic, in denial, disorganized, uncaring, dysfunctional, and unlikely candidates for this kind of treatment—in short, "unreachable." However, these families might well describe traditional clinic-based programs as "unreachable." Clinical programs are often too far away from home, too expensive, insensitive, distant, inflexible in terms of scheduling and content, foreign in terms of language (literally or figuratively), blaming or critical of their lifestyle. A cost–benefit analysis would, in all likelihood, reveal that the costs to these families of receiving treatment far outweigh the potential benefits—even though they do genuinely want to do what is best for their children. Perhaps this population has been "unreachable" not because of their own characteristics, but because of the characteristics and obstacles of the interventions they have been offered.

The paradox is that while, on the one hand, we decry the lack of efficacy of therapy (i.e., PT) with economically disadvantaged families, on the other hand, we also maintain the belief that if we could just do *more psychodynamic therapy* focusing more broadly (i.e., on family dysfunction and parental psychopathology), we would be more effective. But we believe the problem may not lie in the focus of the therapy (i.e., parenting skills vs. family dynamics), but rather in the therapeutic model or approach—namely, a traditional clinic-based model of PT. Before abandoning PT as an intervention with this population, we should examine alternative models of delivering PT which take the broader social context into consideration. If PT is offered in nonstigmatizing locations (as opposed to mental heath centers) and made readily available in communities through churches, schools, and community centers, the programs might well attract more families. PT programs which provide for transportation, day care, meals, flexible scheduling, and attend to some of the obstacles for families getting to and staying involved with programs are likely to be more successful. More research is needed on how programs can be made culturally sensitive and tailored to the specific needs and priorities of the particular parents involved. In general, much more research is needed on ways to promote parental involvement and engagement in PT programs.

Socioeconomically disadvantaged families and rural families are less likely to seek mental health services for children's behavioral problems. This may be due to psychological obstacles such as the stigma associated with seeking assistance for psychological problems. Or it may be due to differences in priorities, or to cultural differences in how behavior problems are viewed and solved within a family. For example, in some cultures there is shame attached to disclosing family problems outside the family which extends to the entire family, relatives, and ancestors. Or it may be the result of an attitude that little can be done about the problem. As we noted earlier, failure to access such services may result from structural obstacles such as difficulty accessing and paying for services, lack of transportation, the distance involved in getting to the service, lack of babysitting for other children, inflexible clinic hours, etc. It is necessary to understand the obstacles that disadvantaged groups experience when accessing services and to develop more effective ways of reaching these families and attracting them to such programs.

The growing ethnic diversity among families in the United States also makes it imperative that we not only recognize and understand different cultural attitudes and practices regarding parenting, but more importantly develop interventions that are culturally informed and appropriate for different ethnic groups. It is important to be cautious about generalizations regarding specific cultural groups, for every parent is different and has his or her own unique history. Nevertheless, it is essential to understand the cultural values and historical factors that are the context for parenting, influencing parents' behavior with their children (Harkness & Super, 1995). For example, parents from certain cultural groups may put a high priority on their children developing habits of obedience, humility, respect for the elders, reliance on family networks, and family interdependence, while parents from other groups may value creativity, personal self-control, and emotional independence. In some cultural groups communication styles are open, volatile, and expressive, while in other groups communication is more indirect and infrequent. Attitudes toward discipline range from strict discipline practices of cultures which value obedience to authority to the permissive discipline practices of cultures which place emphasis on personal autonomy and self-respect. PT research encompassing cultural issues is almost nonexistent (Forehand & Kotchick, 1996). Apart from anecdotal information, we do not know whether certain behavior management strategies (e.g., play, time out, ignoring) are more easily accepted in some cultural groups than others or if a certain therapeutic style would be more effective than another. Finally, mistrust of the majority culture by ethnic minorities can be a barrier to PT. Ethnic minorities walk a fine line between maintaining their cultural history and traditions and adopting the strategies of the European–American culture that are typically associated with success (Coughlin, 1995). This is yet another reason why parenting programs which are collaborative are more likely to be accepted by parents: because parents set their own goals for therapy based on their personal values. Collaborative therapy is inherently more accommodating of cultural differences, whereas noncollaborative therapies are more likely to be shaped by the cultural values and norms of the therapist.

Webster-Stratton has conducted a randomized study to evaluate a prevention program for a multiethnic group of 250 Head Start families, 90% of whom were on welfare. This 9 week, 2 hour parenting program was community-based (held in housing units, churches, and schools) and addressed many of the issues of economically disadvantaged families by providing transportation, day care, dinners, afternoon and evening groups, and parent group support. Since a major theme of the program (in addition to learning parent management skills) was to decrease family isolation by learning effective ways to give and get support (inside and outside the family), parents were paired up to make weekly "buddy" calls. Group leaders called parents weekly. Teachers were also trained in the program and encouraged to provide extra support to families. Visits to classrooms were arranged as well as helping parents write positive notes to teachers.

Preliminary results are promising, with over 85% of those who participated attending over two-thirds of the sessions. In comparison with mothers in the Head Start centers which did not offer this program, mothers made significantly fewer critical remarks, used less physically negative discipline, and were more positive, appropriate, and consistent in their discipline style. Intervention mothers perceived their family service workers as more supportive than did comparison mothers; furthermore, teachers reported that intervention mothers were more involved in their children's education than nonintervention mothers. In turn, intervention children were observed at home to exhibit significantly fewer negative behaviors, less noncompliance, more positive affect, and more prosocial behaviors than children in Head Start centers which did not offer the parent intervention.

Consumer satisfaction with the program was high, with 89% reporting "positive" to "very positive" overall satisfaction, 91% reporting they expected positive results, and 95% saying they would "highly recommend" the program to others. Over 85% of the parents in the intervention condition wanted the program to be longer and to continue into the kindergarten year (Webster-Stratton, 1995). While it cannot be determined precisely what the active ingredient of this intervention was because there was no comparison PT intervention, the data are suggestive of the value of directly targeting social support both within and outside the family as well as eliminating barriers regarding transportation, day care, and food for low-income families.

In another randomized study (Cunningham, Bremner, & Boyle, 1995), families were randomly assigned to either a 12 week clinic-based individual PT (Clinic/Individual) or a 12 week community-based large group PT (Community/Group) or a waiting-list control condition. Families who were significantly more likely to enroll in the Community/Groups were characterized as immigrant families, those using English as a second language, and parents of children with severe behavior problems. Parents in Community/Groups reported greater improvements in behavior problems at home and better maintenance of these gains at 6 month follow-ups. Moreover, Community/Group interventions were six times more cost effective than Clinic/Individual training. This important study suggests the potential for group community PT programs as a valuable resource which may reduce the cultural, linguistic, and family barriers which prevent participation in clinic-based programs.

5.08.5.8 More Complex Models

It has become evident that the etiology of and treatment model for young children's conduct problems are complex and transactional and must involve not only attention to family functioning and parent–child mechanisms but also the other domains of influence we have mentioned—namely, child biological and sociocognitive factors, attachment issues, and the wider contextual influences (Caspi & Moffitt, 1995). While there have been some efforts to study the interrelationship between various types of PT and family contextual factors, there is comparatively little research looking at the interrelationships between PT and child biology, sociocognitive factors, and parent–child attachment.

These interrelationships are important to understand, for the length, breadth, setting, and focus of training needs to be matched to the risk domains affecting the child's problems. For example, if a child has biological and sociocognitive risk factors as well as insecure attachment with his or her parent, and lives in a stressful family environment, he or she will need a far more comprehensive intervention (involving parent and child training as well as teacher training to alter the peer context in the classroom) than a child who has no biological or family risk factors and has not yet developed pervasive conduct problems which have generalized from home to school. The child who has no biological factors and nonpervasive conduct problems (that is, setting specific) may be adequately treated with a basic PT program. On the other hand, the child coming from a family where there are family problems and social context factors such as drug abuse, marital distress, depression, and attachment problems but who has no biological factors will need an intervention that focuses on family interpersonal problems as well as parenting skills. Depending on the parents' willingness and/or ability to benefit from such a comprehensive family intervention, we may need to supplement the family intervention with teacher training and child training. We should undertake research where we identify risk groups and then evaluate levels of intervention—ranging from relatively basic PT programs to more comprehensive programs involving parent, teacher, and child training.

5.08.5.9 Understanding Therapeutic Process Variables

It is clear that there is a need for research evaluating competing models regarding the etiology of childhood conduct problems. There is a further need for research regarding the critical therapeutic change processes (e.g., comparing interventions which focus on promoting parent–child attachment, interpersonal relationships, and the collaborative process vs. those which are more parent behavior skill-based). While PT research in recent years has focused on expanding the content for PT to include broader family issues, it has largely ignored the role of variables having to do with the therapeutic process itself. Yet these variables affect a family's level of engagement in therapy, their level of resistance and the acceptability of parenting strategies by different cultural and ethnic groups. For example, in one of the earliest studies of therapeutic process, Patterson and Forgatch (1985) have highlighted the critical importance of the manner in which the therapist deals with resistance. They showed that when therapists met parent resistance with confrontation and teaching, there was an increase in parental resistance; when the therapist was nonconfrontive, supportive, and nondirective, the resistance decreased. These findings are important, since parental resistance is a major cause of parental drop-out from therapy and failure to make changes. In another study, Patterson and Forgatch (1995) showed a relationship between fathers' confrontational behavior in therapy and lack of change in mothers' discipline strategies, and a relationship between mothers' hopeless and defending behavior and fathers' discipline strategies. In addition, Alexander and his colleagues have examined the influences of therapist characteristics (e.g., gender) and processes on family behavior (Alexander, Waldron, Newberry, &

Liddle, 1988). They have provided extensive work on the notion of therapist "reframing," suggesting that it is a more effective therapeutic process than therapist teaching and reflecting for reducing defensiveness in parents and adolescents (Robbins, Alexander, Newell, & Turner, 1996). Webster-Stratton and Herbert (1994) have emphasized the importance of a collaborative relationship and interpersonal process with parents and a group approach to PT. This collaboration encompasses 10 domains of therapist skills: (i) building supportive and caring relationships; (ii) empowering parents through behaviors such as reinforcing and validating parental insights; (iii) using active teaching skills (e.g., videotape modeling, role-play, rehearsal, parent group and therapist feedback, home assignments); (iv) interpreting (analogies and metaphors), reframing, and persuading; (v) leading and challenging; (vi) prophesizing (anticipating set-backs and successes); (vii) individualizing, generalizing, and contextualizing; (viii) preparing for the long-term; (ix) fostering PT groups as support systems; and (x) building parent support outside the group. Further research regarding the use of these therapy skills is worth pursuing, in order to understand their relationship to parent engagement in PT and to compare their effects with PT programs which do not utilize these strategies.

Patterson and Forgatch (1995) showed that parental social disadvantage, antisocial behavior, and depression were associated with increased parental resistance throughout PT. They proposed that parental resistance could result from four factors: (i) a history of failure in discipline attempts with the child; (ii) parental psychopathology, depression, and antisocial behavior; (iii) stress and social disadvantage; and (iv) the therapist's clinical skills in teaching and confronting parents. These findings suggest the complex interplay between family, contextual, and therapy process factors.

5.08.6 SUMMARY

Despite the evidence concerning the stability of conduct problems stemming from preschool into later life and the effectiveness of family intervention programs, there is an appalling lack of availability of comprehensive training programs for parents of young children with behavior problems. While funds are available for various mental health screening programs for preschoolers, they are rarely available to provide intervention once children with conduct problems are identified. These children have largely been neglected by the mental health community, which has targeted school-age and adolescence for intervention efforts. Preschoolers are offered help primarily if they have more serious cognitive or developmental delays such as mental retardation, or marked psychosocial disadvantage. When young children with conduct problems come to the attention of professionals, they are frequently ineligible for programs or their problems are dismissed as age-appropriate behaviors which are likely to be outgrown.

Not only are there few programs available, even when children have been identified as having ODD or CD, but there are even fewer prevention programs designed to identify high-risk families and to offer training and support when children are toddlers, before conduct problems develop. Gross, Fogg and Tucker (1995) evaluated the 10 week Webster-Stratton basic parenting program with parents of toddlers judged by their parents as behaviorally difficult. Results suggested that PT led to significant increases in maternal self-efficacy, decreases in maternal stress, and improvements in the quality of mother–toddler interactions. Improvements were maintained 1 year later.

Because it is clear that relatively marked behavior problems in preschoolers have long-term developmental consequences for some proportion of children and their families, the need for early intervention programs is obvious—and pressing. Although comprehensive treatment programs for preschoolers may seem costly in the current economic climate, reducing conduct problems in young children will ultimately decrease the need for mental health and educational services later on. The cost of not treating such early problems far outweighs the cost of instituting appropriately targeted intervention programs when children are young.

5.09.1 INTRODUCTION

Play therapy is in a state of transition. Play has been a part of therapy with children since Melanie Klein (1927) and Anna Freud (1927) first began using play techniques in child therapy in the 1930s. As of 1992, play in some form was used in child therapy by a majority of clinicians, as reported by Koocher and D'Angelo (1992). They stated that "play-oriented therapy remains the dominant and most enduring approach to child treatment . . . practiced by clinicians" (p. 458). At the same time, play therapy is being increasingly criticized, along with many types of child therapy, for not having demonstrated treatment efficacy. In truth, there is not a strong empirical base for the effectiveness of play therapy (Phillips, 1985).

Suffice it to state, the empirical base of play therapy has not grown along with the clinical application of play therapy.

Nevertheless, there is an empirical literature in various areas of child psychology that supports the importance of play in child development. Play is involved in the development of many cognitive, affective, and personality processes that are important for adaptive functioning. Unfortunately, the field has not yet learned how to apply this accumulating knowledge base to play therapy. We know much about the role of play in child development, but have not utilized this knowledge in developing intervention and prevention programs that can be evaluated empirically. Research programs need to be developed that expand our knowledge about how play effects change and how we can facilitate play. The main point in this chapter is the thesis that play is an extremely worthwhile intervention approach with children and should be extensively investigated so that we can help children utilize this resource more effectively.

5.09.2 THEORETICAL UNDERPINNINGS

The theoretical underpinnings of play therapy come from two different sources. The first is the theory from the child psychotherapy literature. The second source is the theory and empirical work from the child development literature.

5.09.2.1 Conceptualizations from Child Therapy

In the child therapy literature, three broad functions of play emerge as important in therapy. First, play is a natural form of expression in children. Chethik (1989) refers to the language of play. Children use play to express feelings and thoughts. Chethik states that play emerges from the child's internal life and reflects the child's internal world. Therefore, children use play to express affect and fantasy and, in therapy, to express troubling and conflict-laden feelings. The expression of feelings itself, sometimes termed catharsis, is thought to be therapeutic (Axline, 1947; A. Freud, 1965; Moustakas, 1953). The therapist facilitates this process by giving permission for feelings to be expressed and by labeling the affect. By labeling the affect, the therapist helps to make the feeling less overwhelming and more understandable. In addition, the child feels more accepted as a whole person by the therapist and, in turn, is thought to become more self-accepting.

The child also uses this language of play to communicate with the therapist. It is essential that the therapist understand these communications, so that the therapeutic relationship can develop (Chethik, 1989). The therapist actively labels, empathizes and interprets the play, which in turn, helps the child feel understood (Russ, 1995). For many children, this feeling of empathy from the therapist facilitates change in their interpersonal representations and interpersonal functioning. The importance of expression through play and communication with the therapist is thought to be important by both psychodynamic and client-centered or person-centered approaches.

A second major function of play is as a vehicle for the occurrence of insight and working through. The conceptualization of this function of play is a psychodynamic one. Psychodynamic theory views the emotional resolution of conflict or trauma as a major mechanism of change in child therapy. Children reexperience major developmental conflicts or situational traumas in therapy. Many of these conflicts are expressed in play. The play process itself has been thought of as a form of conflict resolution. For example, Waelder (1933) has described the play process as one in which the child repeats an unpleasant experience over and over until it becomes manageable.

Freedheim and Russ (1992) described the slow process of gaining access to conflict-laden material and playing it out until the conflict is resolved. Erickson (1963) presented the concept of mastery, in which the child uses play to gain mastery over traumatic events and everyday conflicts. During this process, the therapist labels and interprets the play. Although there is controversy in the psychodynamic literature about how much interpretation should occur (Klein, 1955; A. Freud, 1966/1937), there is general agreement that working through and mastery are important mechanisms of change in play therapy.

A third major function of play in therapy is that of providing opportunities to practice with a variety of ideas, behaviors, interpersonal behaviors, and verbal expressions. Because play is occurring in a safe environment, in a pretend world, with a permissive, nonjudgmental adult, the child can try out a variety of expressions and behaviors without concern about real-life consequences. In some forms of play therapy, the therapist is quite directive in guiding the child to try new behaviors. For example, Knell (1993) developed a cognitive behavioral play therapy approach that actively uses modeling techniques and a variety of cognitive behavioral techniques.

It is important to point out that although these three major functions of play occur in normal play situations, the therapist builds on these normal functions by enhancing the play experience. The therapist creates a safe environment, gives permission for play to occur, actively facilitates play, and labels the thoughts and feelings expressed. For the psychodynamic therapist, interpretation specifically aids conflict-resolution. Because there are so many individual differences in play skills and abilities in children, there are many different kinds of play therapy techniques that are utilized.

5.09.2.2 Conceptualizations from Child Development

Conceptualizations from child development theory and research are relevant to the area of play therapy. Play is thought to facilitate both cognitive and emotional development. Children's play is related to a number of cognitive and affective processes that are important in child development (Russ, 1995). There is evidence that play facilitates cognitive and emotional development (see D. Singer & J. L. Singer, 1990, and Russ, 1993, 1995 for reviews). In play therapy, the therapy process uses these change processes, although not yet in any kind of systematic fashion. Research in this area is reviewed later in this chapter.

Play has been linked to the development of cognitive processes important in logical problem solving and in creative problem solving (Singer & Singer, 1990). For example, play has been related to and has facilitated insight ability (Vandenberg, 1980) and divergent thinking ability (Dansky, 1980; Russ & Grossman-McKee, 1990). Both cognitive and affective processes, important in creative thinking, are facilitated through play (Russ, 1993, 1995). In therapy, as both types of problem solving abilities develop, problem solving in everyday life can be enhanced.

Play is also thought to be related to general adjustment. Again, both cognitive and affective processes, important in adjustment, are developed in play. Play helps children learn to express and regulate their emotions. Play helps develop cognitive structures that, in turn, help children to integrate and modulate their emotions.

Children also use play to practice with and try out various coping strategies for different situations (Christiano & Russ, 1996). Children role play different scenarios and generate different solutions to everyday problems and stressful situations. For example, a child might try out different ways to handle teasing from other children or prepare for a frightening situation. In the Christiano and Russ (1996) study, the ability to express emotion and use good fantasy in play was related to the amount and variety of coping efforts children made in a dental situation. Good players also reported less distress.

Traditionally, the play therapist has utilized all of these conceptualizations and mechanisms of change in working with children. The choice of specific techniques and mechanisms of change has depended upon the conceptualization of the case. What is needed for the future are play intervention strategies based on research that are matched to specific types of child populations.

5.09.3 HISTORY OF PLAY THERAPY

The history of play therapy is intertwined with the history of child therapy, and play has been used in different ways in different theoretical approaches (Kessler, 1988). Play was first used in child therapy by therapists in the psychoanalytic tradition. Tuma and Russ (1993) reviewed the psychoanalytic literature in detail. Psychoanalytic techniques were adapted to children by Hug-Hellmuth (1921, 1924), A. Freud (1927), and Burlingham (1932). Play was used to substitute for free association. In addition, the therapist was more responsive and gratifying to the child than the therapist would be with adults, and the child therapist actively worked to develop a positive attachment (A. Freud, 1946). Melanie Klein saw the importance of the communication value of play. She suggested that play for the child was the same as free association for the adult. She advocated active and direct interpretation of the unconscious processes expressed in play. Therefore, the therapist would continually interpret the child's play. A. Freud (1966/1937) also viewed play as a direct expression of fantasy and instincts in a less disguised and more accessible form than in adults. A. Freud was more cautious in her interpretations of the meaning of the child's play. She was also more respectful of the child's defenses than was Klein, and encouraged greater participation by the child. She thought that it was important that therapy be a positive experience for the child and that the child want to come to therapy.

The psychoanalytic approach has evolved into the psychodynamic approach. Psychodynamic therapists base their interventions and techniques on psychoanalytic principles, but therapy is shorter, less frequent (once a week rather than 4 or 5 times a week), has more focused and immediate goals, and is more flexible in incorporating a variety of therapeutic techniques (Tuma & Russ, 1993). Play remains a core part of the therapy process. The use of play in therapy and in child development is a great legacy of the psychoanalytic tradition.

The client-centered and relationship approaches to child treatment also utilized play. Axline (1947), in her nondirective approach, has the therapist focus on play as a major form of communication for and with the child. The therapist strives to understand and empathize with the child's issues. Interpretation of underlying dynamics or impulses is rare, however. The therapist trusts the child's developmental process and striving for self-development. A wonderful introduction to the use of play in child therapy, for beginning therapists of any theoretical perspective, is Axline's *Dibbs in Search of Self* (1964). Moustakas (1953) was another lending theorist in this area who stressed the importance of expression of feelings in play and the importance of the relationship between the child and therapist. Moustakas discussed the importance of the child and therapist experiencing each other (Moustakas, 1992). Genuineness in the relationship is an important aspect of therapy for Moustakas.

Although not usually associated with cognitive behavior therapy approaches, play has been used as a tool within that framework (Kessler, 1988). Meichenbaum (1974) thought that imagery and fantasy could be used to teach children self-control. Knell (1993) has developed cognitive behavioral play therapy techniques that use principles of modeling and reinforcement.

In addition, play techniques have been used in a variety of more specific approaches, such as Gardener's (1971) mutual story-telling techniques and Levy's (1938) release therapy for children who have experience trauma.

Today, as Koocher and D'Angelo (1992) stated, play approaches are the dominant treatment approaches in working with children. Play is used with a variety of child populations, in short-term and long-term approaches, and by a variety of theoretical approaches. Trends in child psychotherapy apply to play therapy as well. Therapy is becoming more specific, more focused, more active, and more theoretically integrated (Freedheim & Russ, 1992).

5.09.4 ASSESSMENT AND CLINICAL FORMULATION

One purpose of psychological assessment is to obtain a developmental picture of the child in specific areas of cognitive and personality functioning. Assessment determines how the child is functioning in areas of basic cognitive processes, object relations, capacity for empathy, internalized conflicts, capacity for delay of gratification, self-esteem, and coping resources (Russ, in press). Ultimately, assessment should help with choosing the optimal form of intervention. Play is frequently a part of the assessment process.

When one has the luxury of time, a battery of psychological tests combined with a play or interview session will usually give the fullest view of a child. Of course, information from the individual assessment of the child should be combined with multiple sources of information from the parents, school, and community. Because managed care has resulted in pressures to move more quickly in clinical practice, one must select carefully which assessment methods to use. Only the most reliable and empirically validated measures should be used.

The fact that most child psychologists use tests that tap different psychological processes is reflected in the results of different surveys of child practitioners. Tuma and Pratt (1982) found that most psychologists in their survey used intelligence tests (primarily the Wechsler Intelligence Scales), achievement measures, and projective tests such as the Rorschach, TAT, and drawings. Archer, Maruish, Imhof, and Piatrowski (1991), in a survey focusing on psychological assessment of adolescents, found that the most frequently used tests were the Wechsler Intelligence Scales, the Rorschach (ranked second overall), Bender-Gestalt, TAT, Sentence Completion, and the MMPI. Of those respondents who used a standard assessment battery (139 of 165), the most frequently used measures were the Wechsler, Rorschach, and TAT.

When using a standard battery, different processes are measured by different tests (Tuma & Russ, 1993). Measures of intelligence and perceptual motor functioning (such as the Bender-Gestalt) give information about basic cognitive functioning. Even if there is not a specific question about school performance, the intelligence test is valuable because it assesses how well the child is functioning in a variety of cognitive and perceptual areas. Intelligence tests provide an anchor for a developmental assessment.

Projective tests give information about the personality structure and personality dynamics of the child. Play and interview information are useful for this purpose as well. Frequently, the Rorschach and a story-telling projective technique (e.g., the TAT, Children's Apperception Test or CAT, and Roberts Apperception Test for Children) will be used together.

The Rorschach is especially valuable in describing personality structure (Exner, 1986). Exner discussed how the Rorschach reveals the organizing principles that the individual uses to deal with the world. This is true of children as well as adults. The Rorschach assesses reality testing, the capacity to perceive what is commonly perceived in situations, and how affect influences cognitive functioning. It also assess how the child experiences the world in terms of availability of affect, capacity to experience negative affects, and internal representations of other people.

Projective tests that involve telling stories complement the Rorschach by assessing personality dynamics. The child's wishes, fears, conflicts, and specific areas of emotional distress can emerge. Increasingly available are projective tests containing stimuli appropriate for younger children and ethnic minorities. Drawings and fantasy play can also be used as diagnostic instruments which are especially valuable in revealing personality dynamics.

Projective tests are being rediscovered with the growing focus on the development of object relations as a key element in a child's development. Projective tests are especially suited to assessing object relations. In a review of the literature, Stricker and Healey (1990) defined object relations as concerning "the cognitive, affective, and emotional processes that mediate interpersonal functioning in close relationships" (p. 219). Understanding the developmental level of the child's object relations gives clues to the interpersonal world of the child and offers a framework for explaining interpersonal difficulties the child may be having. Stricker and Healey (1990) also reviewed the major Rorschach-based and TAT-based object relations scales. These scales are relatively new and are still being validated. Interpersonal content has always been part of projective tests, but these new scales and the growing theoretical literature on object relations enable us to develop a more comprehensive understanding of this area by means of a more systematic evaluation of this variable.

Projective tests have been criticized for their lack of demonstrated validity (Dawes, 1994). However, a growing body of construct validity studies on the Rorschach (Weiner, 1996) and story-telling techniques (Westen, 1991) are available and should serve as a guide for when projective tests are appropriate.

Observer rating scales and self-report instruments round out the picture by offering well-validated diagnostic information about the child, compared with their same-aged peers.

5.09.4.1 Assessing Children's Play

Assessing children's play is a valuable addition to a standard test battery. Although many young children cannot readily engage in an interview, they can engage in play. Until the early 1990s there were very few standardized measures of children's play available. Schaefer, Gitlen, and Sangrund (1991) have reviewed the growing number of current play measures. As these play measures become better known and as their reliability and validity is ascertained, we can begin to assess play in a systematic way prior to, during, and after treatment. The development of play assessment instruments is an important step for the field. A formal assessment of play could tell us how well the child plays; assess how well the child could use play in therapy; identify the important conflict areas; assess how well affect is expressed and is regulated; determine how constricted the child's fantasy is; assess the development of internal representations; and assess the child's overall cognitive organization. Some of the information would supplement other test information and some would be unique. For example, the best way to determine how well a child can use play in therapy is to observe the child at play.

One possible instrument for assessing play is the Affect in Play Scale (Russ, 1987, 1993). In order to study affect in play and its correlate the Affect in Play Scale was developed by Russ and her students. This scale consists of a standardized puppet play task and specific criteria for a rating scale. The play task utilizes two neutral looking puppets, one boy and one girl and three small blocks that are laid out on a table. It is administered individually to the child. The play task is appropriate for children from 5 to 10 years of age. The instructions ask the child to play with the puppets any way he or she likes for five minutes. The play is videotaped. The instructions can be altered to pull for specific affective themes such as aggression or happiness. An extensive manual has been developed for rating the play. The Affect in Play Scale measures the amount of affect, type of affect, variety of affect, intensity of affect, comfort, quality of fantasy, imagination, and affective integration in the play. There are 11 possible affective categories: Happiness/Pleasure; Anxiety/Fear; Sadness/Hurt; Frustration/Displeasure; Nurturance/Affection; Aggression; Oral; Oral Aggression; Anal; Sexual; and Competition. Any verbal or physical expression between the puppets that reflects an affective category is rated as one affective unit. For example, if one puppet says to the other "I don't like you" it would be scored for one unit of aggressive content.

The Affect in Play Scale has good interater reliability, internal consistency, and good stability of scores across different samples of children. The scale has been used with public school, parochial school, middle-class suburban and inner city populations and has a growing body of validity studies. A review of the Affect in Play Scale and the manual can be found in Russ (1993). This scale could also be used as a measure of change in play intervention research and in play psychotherapy.

It is important to note that for many of the play measures available, including the Affect in Play Scale, play does not relate to traditional IQ measures (Russ & Grossman-McKee, 1990; Singer, 1973). Most of this research has been with children of normal intelligence. Children with major cognitive deficits should also show serious deficits in play skills. Nevertheless, it is important to have measures of children's fantasy and cognitive organization that are relatively independent of intelligence.

Play assessment is well-suited to a repeated measure design, (Russ, in press-b). Changes in the quality of play or the themes in play should occur during therapy. Different types of changes should occur for different types of children. For example, the constricted child should express more affect in play after therapy. The acting-out child should show better modulation of affect in play after treatment. Play measures should be sensitive to change processes in psychotherapy. Shirk and Russell (1996) have stressed the importance of developing measures that are sensitive to specific processes that are being addressed in psychotherapy. Play assessment can focus on cognitive, affective, and interpersonal processes important in psychotherapy.

The general assessment process should help the therapist formulate a diagnostic picture and assess the child's motivation for treatment, capacity to establish a good relationship, and ability to use play and/or verbalization. It should help decide what type of intervention to use, what specific process or symptom should be targeted, and treatment goals. Major mechanisms of change and techniques to bring about those changes should be identified. This leads to the discussion of intervention procedures and mechanisms of change.

5.09.5 INTERVENTION PROCEDURES AND PROPOSED MECHANISMS OF CHANGE

The concept of play psychotherapy is a bit of a misnomer because most psychotherapy with children is a mix of play and talk (Russ, 1995). Play is a tool which can be used in therapy for a variety of purposes. If and how play is used with a particular child in therapy depends upon the child's ability to use play, developmental level, age, ability to verbalize, and the overall treatment approach. In general, play therapy occurs within the context of the overall treatment plan.

In most forms of play therapy, the child and therapist meet individually once a week for 45–50 minute sessions. The mutual agreement between the child and the therapist is that the therapist is there to help the child express feelings and thoughts, understand causes of behavior, and form a relationship with the therapist (Freedheim & Russ, 1992). Traditionally, in both psychodynamic and client-centered approaches, the child structures the therapeutic hour by choosing the topics, forms of play, and setting the pace of therapy. In most cases, individual work with the child is only one part of the treatment program. Parent guidance and education, family sessions, and work with the school usually occur simultaneously with individual child therapy.

5.09.5.1 Issues in Using Play in Therapy

A number of practical issues arise in working with children in play therapy. Ideally, a psychological assessment will have been carried out so that the therapist has identified treatment goals and has developed a treatment plan. The therapist should have determined how much play will be utilized in the therapy, as well as the nature of the play to be encouraged. Usually, play approaches should be considered for children from 4 to 10 years of age.

5.09.5.1.1 How to get started

Many children need help initiating the play process. The therapist usually starts by telling the child that they can play or talk, and shows the child the toys and play materials that are available. Although many children go right to it, many others are reticent. The therapist might tell the child to pick one thing, and start with that or the therapist could pick something for the child. Clay and drawing material are good starters. As a last resort, the therapist might start with something themselves, and have the child join in.

5.09.5.1.2 Kinds of play materials

Most therapists agree that unstructured play materials that can encourage the use of fantasy and imagination are ideal. Toys that leave much room for individual expression are most appropriate for play therapy. Examples of relatively unstructured toys and material are: clay, crayons, cars, trucks, puppets, dolls, doll houses, and legos. Games such as checkers do not encourage free expression, and are not ideal for traditional play therapy. The child is often asked for suggestions of other toys that might be useful and encouraged to bring toys in from home. Different children use different media for expression and it is important to have a variety of items and to individually tailor what is available.

5.09.5.1.3 How much to engage in play

One recurring dilemma is how much the therapist should engage in the child's play. The amount of direction and activity by the therapist depends upon the general theoretical approach. In more traditional client-centered and psychodynamic approaches, the therapist tries not to play with the child, but rather to observe and comment on the child's play. Many children will eventually become comfortable playing in this way. Some children need more engagement by the therapist. With those children, the therapist tries to follow the lead of the child. The therapist might put on one of the puppets and play, but follow the lead of the child in choosing the topic and setting the dialogue.

In more directive approaches, such as cognitive-behavioral play therapy (Knell, 1993), the therapist will play in a very directive fashion. The therapist might put on a play, modeling adaptive coping strategies for an issue that the child is dealing with.

5.09.5.1.4 How much to interpret

An optimal amount of interpretation of the child's play would facilitate the play process and help the child understand his or her thoughts, feelings, and behavior. Too much interpretation will stop the play process. Most therapists today would agree with A. Freud (1976) that the child's defenses should be respected. Timing of interpretations is as important in child therapy as in adult therapy.

5.09.5.1.5 How to set limits

For play to be a safe mode of expression, limits about how to play are essential. If rules need to be set, then they should be set. Toys cannot be broken and the therapist cannot be a target for affective expression. Alternative modes of expression through play should be facilitated. For example, the child can be encouraged to verbalize anger at the therapist or to have the puppets fight it out in a pretend mode.

5.09.5.2 Mechanisms of Change in Therapy

How one uses play in the therapy depends upon how one conceptualizes the specific mechanisms of change to be used in the therapy. Freedheim and Russ (1983, 1992) identified six major mechanisms of change that occur in individual child psychotherapy. These mechanisms were based on those identified by Applebaum (1978) and Garfield (1980) in the adult literature. Different mechanisms of change are utilized in different types of psychodynamic psychotherapy with different types of childhood disorders. However, there is rarely a pure type of psychotherapy and frequently all of these mechanisms may occur in any one case. These mechanisms of change are thought to be universal and to cut across various theoretical approaches to psychotherapy. The specific role of play in these mechanisms was discussed by Russ (1995).

(i) Catharsis and Labeling of Feeling. Through talk and play, children express feelings and release emotion. This release of emotion has long been thought to be therapeutic (Axline, 1947, A. Freud, 1965; Moustakas, 1953). In addition, by labeling affect, the therapist helps to make the feeling less overwhelming and more understandable. Often, the labeling of affect occurs during pretend play. By saying to the child that the puppet is feeling angry, the therapist connects a label to a feeling state. Words help to put feelings into a context for the child, thus making the feelings less overwhelming.

(ii) Corrective Emotional Experience. The therapist accepts the child's feeling and thoughts. Often, the child's learned expectations are not met and a corrective emotional experience occurs (Kessler, 1966). For example, the automatic connection between the child's angry feelings towards father and resultant anxiety should gradually decrease as the therapist helps the child accept the feeling and understand the reasons for the anger. The therapist is not punitive, and is accepting of the child's having angry feelings. Often, these feelings are expressed through play.

(iii) Insight and Working Through. The emotional resolution of conflict or trauma is a major mechanism of change in play psychotherapy. One goal of the therapist when utilizing this mechanism of change is to help the child reexperience major developmental conflicts or situational traumas in therapy. Frequently, play is the vehicle for this working through process. Cognitive insight into origins of feelings and conflicts, causes of symptoms, links between thoughts, feelings, and actions is a goal of psychotherapy when underlying conflicts are a major issue (Sandler, Kennedy, & Tyson, 1980; Shirk & Russell, 1996). Verbal labeling of unconscious impulses, conflicts, and causes of behavior helps lend higher order reasoning skills to understanding problems. However, in many cases, especially with young children, cognitive insight does not occur. Rather, emotional reexperiencing, emotional working through, and mastery do occur and result in symptom reduction and healthy adjustment. This is an important point and is an often overlooked mechanism of change in child treatment. Messer and Warren (1995) also state that the goal of making the unconscious conscious needs to be modified in child play therapy with many children. In Erikson's (1963) concept of mastery, the child uses play to gain mastery over traumatic events and everyday conflicts. Resolving conflicts through play is part of normal child development. Waelder (1933) described the play process as one in which the child repeats an unpleasant experience over and over until it becomes manageable. As he puts it, the child "digests" the event. Freedheim and Russ (1992) describe the slow process of gaining access to conflict-laden material and playing it out until the conflict is resolved. The therapist helps guide the play, labels thoughts, feelings, and events, and makes interpretations to facilitate conflict resolution and the working through process. Because cognitive insight is not necessary for conflict resolution to occur, the amount of interpretation should be carefully considered by the therapist. This is especially true of interpretation of symbols in the play or of deeply forbidden wishes. Mild interpretations that link feelings and thoughts to behavior and that spell out cause and effect are especially helpful.

(iv) Learning Alternative Problem-Solving Techniques and Coping Strategies. The therapist, in a more directive approach, helps the child think about alternative ways of viewing a situation and generate problem-solving strategies. Role-playing and modeling of coping strategies are used. Practice with a variety of verbal expressions and interpersonal behaviors can occur in a safe, pretend play situation. For example, D. Singer (1993) gives examples of modeling techniques during therapy. Knell (1993) teaches the child new strategies for coping with feelings and situations.

(v) Development of Internal Structure. Many children have structural deficits that result in problems with self/object differentiation, interpersonal functioning, self-esteem regulation, impulse control, object constancy, and separation of fantasy from reality. In these children, there are major deficits in underlying cognitive, affective, and interpersonal processes. Structure-building approaches are based upon conceptualizations by Mahler (1968) and Kohut (1977) and view the therapist as being a stable, predictable, caring and empathic figure. Development of good object relations is a major goal of play therapy with these children. Gilpin (1976) stressed that the role of the therapist is to become an internalized object. The relationship between the therapist and child is probably the most important aspect of therapy in helping this process to occur. Genuine understanding and expression of empathy by the therapist is a major technique that enables the child to develop. Play is important here as a form of communication in that the therapist can empathize with the child's expressions. The major change that occurs is through the relationship with the therapist that facilitates developing interpersonal representations in the child.

(vi) Nonspecific Variables. Nonspecific variables function in child therapy as they do in adult therapy. Expectation of change, hope, awareness of parental concern, no longer feeling so alone, are all factors that contribute to change in therapy.

5.09.5.3 Mechanisms of Change in Different Types of Therapy

5.09.5.3.1 Psychodynamic play therapy

Different types of therapy emphasize different mechanisms of change. Different techniques are used to foster the different mechanisms. The form of therapy most associated with the psychodynamic approach is insight-oriented therapy, and it is most appropriate for the child with anxiety and internalized conflicts (Tuma & Russ, 1993). This approach is appropriate for children who have age-appropriate ego development, show evidence of internal conflicts, have the ability to trust adults, have some degree of psychological-mindedness, and can use play effectively. Insight-oriented therapy is most often recommended for internalizing disorders including many of the anxiety disorders and depressive disorders. Children with internalizing disorders often experience internal conflicts and have good ego development and good object relations. An insight-oriented approach with a focus on conflict resolution is most appropriate for internalizing disorders. Many children in this broad category are good players and can easily engage in play in the therapy situation.

The goals of insight-oriented therapy are to help the child resolve internal conflicts and master developmental tasks. The major mechanism of change is insight and working through. Through the use of play and interpretation from the therapist, the child "calls forth forbidden fantasy and feelings, works through and masters developmental problems, and resolves conflicts" (Freedheim & Russ, 1983). Active interpretation of the child's play, expressions, and resistances is a major technique. For example, the therapist might interpret a child's stealing from mother's purse as an expression of anger at feeling neglected by her after the birth of a baby brother.

Insight and working through can also be helpful for a child with good inner resources who has experienced a specific trauma (such as the loss of as a parent). Altschul (1988) described the use of psychoanalytic approaches in helping children to mourn the loss of as a parent. In this application, Webber (1988) stressed that the therapist must first address the question of whether the child can do his or her own psychological work. If not, therapy can be a major aid in the mourning process.

A second major form of psychotherapy is the structure-building approach, which is used with children with structural deficits and major problems in developing good object relations. For children with impaired object relations, self/other boundary disturbances, and difficulty distinguishing fantasy from reality, the therapist uses techniques that foster the development of object permanence, self/other differentiation, and modulation of affect. The major mechanism of change is the building of internal structure such as object relations. Anna Freud (1965) described the development of object relations through a continual process of separation from the significant adult, usually the mother. Mahler (1975) elaborated on the separation-individuation process and described the development of object constancy and object representations. As Blank and Blank (1986) stressed, Mahler's concept of separation-individuation represented a new organizing principle to development. Object relations is not just another ego function, but plays a major role in the organization of intrapsychic processes.

The growing theory on the development of object relations is a new phase in psychoanalytic theory construction (Tuma & Russ, 1993). Good object relations involve well-developed object representations. The child must invest in the mental representation of the loved external object. Children who have inadequately developed object relations have structural deficits that impair a variety of functions. This impairment is evident with psychotic and characterological disorders. Children with severely impaired object relations, such as borderline children, have early developmental problems with a mix of severe dysfunction in the family and in the case of borderline children, perhaps a genetic predisposition. These children require a structure-building psychotherapeutic approach.

In this approach, empathy on the part of the therapist (as a general relationship factor) (Kohut & Wolfe, 1978) is a much more important intervention than is interpretation (Russ, 1995). Chethik (1989) provided an excellent discussion of psychotherapy with borderline children and narcissistically disturbed children. He pointed out that many of the therapeutic techniques are supportive in that they "shore up" defenses. The problems characteristic of borderline and narcissistic children are early developmental problems usually stemming from severe disturbance in the parent-child interaction. Kohut and Wolfe (1978) discussed the failure of empathy from the parent that is a major issue in the faulty parent-child interaction. Because of the frequency of this defect in parent-child relations, empathy from the therapist around the history of empathic failure becomes an important part of therapy. Frequently, help with problem solving and coping is also used with these children. Therapy with these children is usually long-term (one to two years) to be effective.

A third form of psychodynamic therapy is supportive psychotherapy, most appropriate for children with externalizing disorders. These children frequently act-out, have antisocial tendencies, and are impulse-ridden. The broad syndrome of externalizing disorders includes labels of acting-out, antisocial, character disorders, attention deficit disorders, and conduct disorders. Theoretically, psychodynamic theory views these children as having major developmental problems. These children have not yet adequately developed the processes necessary for delay of gratification. In addition, these children are frequently egocentric, demonstrate an absence of shame and guilt, and their ability to empathize with others is impaired. Kessler (1988) has recommended that structured, supportive therapy is more helpful to these children than any other kind of psychodynamic therapy. Therapy focuses on the here and now and on the development of problem-solving skills and coping resources. For example, the therapist might role-play with the child about how to handle teasing at school or how to be assertive with parents.

At this point, given the effectiveness of behavioral and cognitive-behavioral approaches in working with externalizing disorders, it appears that supportive psychodynamic psychotherapy is not the treatment of choice (Russ, 1995). It should only be used as a supplement to other treatment approaches in order to work on a specific issue.

Chethik (1989) has a thorough discussion of the use of play within the psychodynamic approach. As reviewed by Tuma and Russ (1993), he describes four stages of play development within psychotherapy (see Chethik, 1989, pp. 48–66 for a more detailed description).

(i) Initial period of nonengagement. Setting the stage-developing expectations, structure, and limits. The therapist first defines how play will be used for communication and how the child's internal life combined with play materials will express and replay the child's internal life for them both. "Meaningful play" must be developed, sometimes by varying the structure. This means that the overinstinctualized child (e.g., impulsive, fast to react) may require more structure, whereas the underinstinctualized child (e.g., obsessive, slow to react) may need to be encouraged to express instinctual life in play.

(ii) Early phase of affective engagement. As play develops, the therapist begins to share metaphors that emerge, and the child becomes attached to both the process and the therapist. When this happens, the therapist can then permit regressions by becoming a player in the play (by doing what the child asks him or her to do). The child can then express his or her instinctual life more freely because he or she identifies with the therapist and the therapist's sanctions. The safety the child feels in expressions are further ensured by imposing boundaries (e.g., by keeping forbidden expression in the room or having clean-up time). The unstructured quality, the accepting attitudes, and the boundaries all foster early "regression in the service of the ego." As the child feels more comfortable and masters anxiety, his or her play becomes more open. Those expressions at first defensively avoided are now displayed in full view of the therapist.

(iii) Emergence of central fantasies. As the process intensifies, the child elaborates highly invested fantasies in play. Repetitive play (characterized by the "compulsion to repeat") begins to deal with past traumatic and difficult situations. In the therapy process, however, the past has a changed outcome: acceptance of the play and interpretations by the therapist permit new solutions, either verbally or through play. Now the situation is in the control of the child.

(iv) Period of working through. Specific symptoms or behaviors often have more than one meaning. A working through period is necessary where a series and variety of interpretations are made to bring about change in a symptom. Symptoms are discussed in different contexts until all the meanings are worked out.

5.09.5.3.2 Cognitive-behavioural play therapy

Principles of cognitive-behavioral therapy and play therapy have been integrated into one approach. Knell (1993) introduced the concept of Cognitive-behavioral play therapy (CBPT) in which cognitive and behavioral interventions are incorporated within a play therapy paradigm. Play itself is used to resolve problems.

Knell (1993) identified six properties of CBPT:

(i) The child is involved in the treatment through play.

(ii) CBPT focuses on the child's thoughts, fantasies, and environment.

(iii) CBPT provides a strategy or strategies for developing more adaptive thoughts and behaviors. The child is taught coping strategies for feelings and for situations.

(iv) CBPT is structured, directive, and goal oriented, rather than open-ended.

(v) CBPT incorporates empirically demonstrated techniques, such as modeling.

(vi) CBPT allows for an empirical examination of treatment.

Knell (1993) also identified similarities and differences between CBPT and more traditional psychodynamic or client-centered approaches. Similarities included: the importance of the therapeutic relationship; communications occur through play; therapy is a safe place; and play provides "clues" to understanding the child.

Differences suggested that in CBPT therapy is more directed and goal oriented; the therapist is involved in choosing play materials; play is used to teach skills and alternative behaviors; interpretations are given by the therapist (similar to psychodynamic but different from client-centered) and praise is a crucial component. It is also more empirically based.

These similarities and differences are true for the "classic" forms of psychodynamic play therapy. However, new forms of psychodynamic play therapy are also being developed that are more goal oriented. For example, Chethik's (1989) focal therapy is focused on specific problems and is of short duration. Messer and Warren (1995) have called for psychodynamic approaches to be adapted to short-term goal oriented frameworks. They state that short-term therapy is a frequent form of psychodynamic intervention and that play is a good vehicle for change. Still, Knell's (1993) approach is a thoughtful integration of different theoretical approaches and techniques and is an excellent model for how to integrate treatment approaches.

Bodiford-McNeil, Hembree-Kigin, and Eyberg (1996) have developed a CBPT approach that is focused on a specific population of children. Their short-term play therapy for disruptive children utilizes the principles of CBPT but tailors the approach for disruptive children. Their approach is also set for 12 sessions with very specific goals and objectives per session. For most of the 12 sessions, the first half of the session is task-oriented and the second half is child-directed play. The therapist uses a variety of techniques such as praise, reflection, imitation of play, questions, interpretation, reinforcement, and contingent attention. The therapist follows the child's lead in the play, but also tries to move it as quickly as possible. By the eighth session, the parent is included in the process and is coached to facilitate the child's play. Parents practice their play sessions at home with the child. Parents are taught most of the play facilitation skills, but not that of interpretation, which belongs in the domain of psychotherapy. Bodiford-McNeil et al.'s approach integrates techniques from a variety of theoretical approaches and chooses those that are most effective for a specific population, that is disruptive children. It is a good example of developing an integrated approach for a specific population.

5.09.5.4 Change Processes in Play in Child Development

Play facilitates change and growth in a variety of cognitive, affective, and personality processes. Play fosters growth in these areas in normal child development. These change mechanisms are thought to operate in the play therapy process, although not usually in a targeted and systematic fashion. The empirical literature in the play and child development area is relevant to the play psychotherapy literature. Russ (in press) has a more detailed review of the play and child development literature, with a specific focus on creativity.

5.09.5.4.1 Play and cognitive processes

Research has supported a relationship between play and creative cognitive processes (Dansky, 1980; Fein, 1981; Russ, in press-a). Saltz, Dixon, and Johnson (1977) found that fantasy play facilitated cognitive functioning on a variety of measures. They theorized that fantasy play is related to cognitive development because of the involvement of representational skills and concept formation. Singer and Singer (1976) concluded that the capacity for imaginative play is positively related to divergent thinking, verbal fluency, and cognitive functioning in general.

Early research on play and creative problem solving investigated play and insight ability. In a series of studies, Sylva, Bruner, and Genova (1976) concluded that play in children 3–5 years of age facilitated insight in a problem solving task. In one study, they had three groups of children. One group played with the objects which were later used in the problem-solving task. A second group observed the experimenter solve the problem. A third group was exposed to the materials. Significantly more children in the play and observation groups solved the problem than in the control group. The play group was more goal oriented in their efforts on the task and was more likely to piece together the solution than the other groups.

Vandenberg (1978) refined the experimental methodology of the Sylva et al. studies and used a wider age group, 4–10 years of age. The experimental group played with the materials to be used in the problem solving task and the control group was asked questions about the material. Children were also given hints as to the solution. The play group did significantly better on one of the two insight tasks following the intervention. Six and seven-year-olds benefited most from the play experience. Vandenberg concluded that the relationship between play and insightful tool-use was mediated by age and task characteristics. In a review of the insight and play studies, Vandenberg (1980) concluded that all studies in the area had the consistent finding that play facilitated insightful tool use and enhanced motivated task activity.

There is a substantial body of studies that has found a relationship between play and divergent thinking. Divergent thinking is the generation of a variety of ideas and alternative solutions to problems (Guilford, 1968). Divergent thinking is especially important in creativity. Singer and Singer (1990) viewed play as a way of practicing divergent thinking ability. Singer and Rummo (1973) found a relationship between play and divergent thinking in kindergarten boys. Pepler and Ross (1981) found that play was related to divergent thinking. Feitelson and Ross (1973) found that thematic play facilitated creative thinking. Experience with a divergent thinking task facilitated performance on divergent thinking tasks in a study by Pepler (1979). In that study, performance on the divergent thinking task could be predicted from the expression of symbolic and representational play. Hughes (1987) studied four- and five-year-olds and reported that manipulative play with objects facilitated divergent thinking, but only for the number of nonstandard responses on the Alternate Uses Test.

Wallach (1970) stressed the importance of the relationship between divergent thinking and fantasy. Subjects who scored well on divergent thinking tests produced novel stories on the TAT (Maddi, 1965) and engaged in daydreaming activity (Singer, 1973). Wallach (1970) proposed that breadth-of-attention deployment is the underlying variable involved in divergent thinking tasks. As Kogan (1983) pointed out, breadth-of-attention deployment refers to a scanning of the environment and memory in an associational manner. Both creativity and fantasy may share breadth-of-attention deployment. From a cognitive perspective, this variable could also account for the play-creativity link.

In several important studies, play facilitated divergent thinking in preschool children (Dansky, 1980; Dansky & Silverman, 1973). In particular, Dansky and Silverman found that children who played with objects during a play period gave significantly more uses for those objects than did control subjects. In a later study, Dansky (1980) found that make-believe play was the mediator of the relationship between play and divergent thinking. Free play facilitated divergent thinking, but only for children who engaged in make-believe play. Also, in this second study, play had a generalized effect in that the objects in the play period were different from those in the test period. These two studies are important because they are experimental studies that show a direct effect of play on divergent thinking.

Dansky's (1980) theoretical rationale for hypothesizing that play would facilitate divergent thinking was that the process of free combination of objects and ideas involved in play is similar to the elements involved in creative thinking. Dansky (1980) speculated that the free symbolic transformations inherent in pretend play helped create a temporary cognitive set toward the loosening of old associations. These ideas are consistent with the work of Sutton-Smith (1966, 1992) who stressed the role of play in the development of flexibility in problem solving. Play provides the opportunity to explore new combinations of ideas and to develop new associations for old objects. The object transformations that occur in play help to develop the capacity to see old objects in new ways. The capacity to see old objects and ideas in new ways should also aid in developing transformation abilities (i.e., the ability to break out of an old set and see a new solution to a problem). Kogan (1983) also suggested that children's play behavior involves a search for alternate modes of relating to the object, a process similar to searching for alternate uses for objects in divergent thinking tasks.

Pellegrini (1992) also identified flexibility as one link between play and creativity. In a study of third and fifth grade boys, flexibility in rough and tumble play was predictive of a variety of prosocial problem solving responses. Pellegrini proposed that in play, children recombine behaviors and develop flexible strategies. A varied problem solving repertoire aids in social competence. Saracho (1992) obtained results that also support a link between play and flexibility. She found that field independent children engaged more in play than did field dependent children and concluded, from observing the children's play, that the field independent children were exhibiting cognitive flexibility.

Until 15 years ago, the research on play and creativity had focused on cognitive variables as the explanatory mechanisms underlying the observed relationship. As discussed, explanations have included practice with divergent thinking, the recombination of objects and ideas, symbolic transformations, breadth-of-attention deployment, and the loosening of old cognitive sets or cognitive flexibility.

5.09.5.4.2 Play and affective processes

Play also facilitates affective development. Affect may also be involved in the link between play and creative problem solving. Play and affective processes are just beginning to be studied, mainly because of the difficulty in measuring affective processes in play. In general, the empirical study of affective expression in children is a young area (Masters, Felleman, & Barden, 1981). The theoretical explanations for the links between affect, play, and creativity have been in existence for some time, although research that tests theory is relatively recent.

The first major theoretical explanation for the relationship between affect and creativity was that of psychoanalytic theory, which proposed that controlled access to primary process thinking facilitated creativity. Primary process thinking was first conceptualized by S. Freud (1915/1958) as an early, primitive system of thought that was drive-laden and not subject to rules of logic or oriented to reality. Another way to view primary process thought is as affect-laden cognition. Russ (1987, 1993, 1996) proposed that primary process thought is a subtype of affect in cognition. Primary process content is material around which the child had experienced early intense feeling states (oral, anal, aggressive, etc.) According to psychoanalytic theory, primary process thinking facilitates creativity (Kris, 1952). Children and adults who have controlled access to primary process thinking should have a broader range of associations and be better divergent thinkers than individuals with less access to primary process. S. Freud's (1926/1959) formulation that repression of "dangerous" drive-laden content leads to a more general intellectual restriction predicts that individuals with less access to affect-laden cognitions would have fewer associations in general. Thus, children who are more expressive of and open to affective content would develop a richer, more complex store of affect-laden memories. This richer store of memories would facilitate divergent thinking and transformation abilities because it provides a broader range of associations and more flexible manipulation of images and ideas.

Primary process content can be expressed in play. As Waelder (1933) has noted, play is a "leave of absence from reality" (p. 222), and is a place to let primary process thinking occur. Play can be important in the development of primary process thought and, in turn, foster creative thinking.

Primary process theory is consistent with Bower's (1981) conceptualization of affect and memory processes (see Russ, 1993). The work on mood and memory suggests that the search process for associations is broadened by the involvement of emotion. Russ (1993) proposed that if primary process is thought of as mood-relevant cognition, then it could fit into a mood and memory theoretical framework. When stirred, primary process content could trigger a broad associative network. Primary process content was stored into the memory system when emotion was present. Access to this primary process content would activate emotion nodes and associations, thus broadening the search process.

Fein (1987) views affect as intertwined with pretend play and creativity. Fein (1987) viewed play as a natural form of creativity. She studied 15 children who were master players and concluded that good pretend play consists of five characteristics.

(i) *referential freedom*. The "as if," concept is important in that one object is treated as if it were another, one person functions as if they were another, time and place is as if it were different. Object substitutions and transformations occur.

(ii) *denotative license*. The child takes a divergent stance with respect to actual experience. There are pretend events, not just object substitution in an accurate account of events.

(iii) *affective relations*. Symbolic units represent affective relationships such as "fear of, love for, anger at." Fein proposed an affective symbol system that represents real or imagined experience at a general level. These affective units constitute affect-binding representational templates which store salient information about affect-laden events. The units are "manipulated, interpreted, coordinated and elaborated in a way that makes affective sense to the players" (p. 292). These affective units are a key part of pretend play and are especially important for creative thinking. Fein stated further that divergent thinking abilities like daydreams, pretend play, or drawing can activate the affective symbol system.

(iv) *sequential uncertainty*. The sequence of events in pretend play has a nonlinear quality.

(v) *self-mirroring*. Children are aware of the pretend, nonreal quality of the play. The self is observed from a distance through the play.

One of Fein's (1987) major conclusions is that creative processes cannot be studied independently of an affective symbol system An affective symbol system is activated in pretend play and is probably facilitated through pretend play. The concept of affective symbols is consistent with the concept of primary process. Primary process content is proposed to be stored in the affect symbol system.

Vygotsky (1930/1967) is also a major theoretician in the area of affect, play, and creativity. He presented a rich conceptualization of play and creativity. Smolucha (1992) has translated and integrated Vygotsky's major papers on the topic of creativity. From her review of his work, a major premise in Vygotsky's theory is that imagination develops out of children's play. He stated: "The child's play activity is not simply a recollection of past experience but a creative reworking that combines impressions and constructs from them new realities addressing the needs of the child" (1930/1967, p. 7). Through play, children develop combinatory imagination (i.e., the ability to combine elements of experience into new situations and new behaviors). Combinatory imagination is significant because it can contribute to artistic and scientific creativity.

Morrison (1988) placed cognitive-affective development within an interpersonal framework. The cognitive integration of affect occurs within safe interactions with parents. Representations of self and others are fused with affect. In play, the child reconstructs past experience and explores definitions of the self. Old metaphors are constantly reworked. In this way, the child develops reflective thought. Conflicts from early interpersonal experience can be a major source of creative thinking in that the metaphors of early experience are reworked in creative acts. Santostefono (1988) also stressed the importance of play in metaphor construction. The process of constructing and negotiating metaphors is creative and can lead to later creativity.

Russ (1993) reviewed the affect and creativity literature and proposed five categories of affect that emerged as important in the creative process: access to affect-laden thoughts; openness to affect states; affective pleasure in challenge; affective pleasure in problem solving; and cognitive integration and modulation of affect. The question of whether or not these five categories are truly separate dimensions of affect needs to be investigated systematically. In Russ' model of affect and creativity, these affective processes are related to specific creative cognitive processes. The links between the processes are based on theory and the empirical literature. Two broad affective processes are access to affect-laden thoughts and openness to affect states.

Access to affect-laden thoughts is the ability to think about thoughts and images that contain emotional content. Affective fantasy in daydreams and in play are examples of affect-laden thoughts. Thoughts involving emotional themes such as aggressive and sexual ideation illustrate this kind of blending of affect and cognition. The psychoanalytic concept of primary process thinking is also an example of emotion-laden thinking (see Kris, 1952; Dudek, 1980; Rothenberg, 1990).

Openness to affect states is the ability to feel the affect itself. Comfort with intense affect, the ability to experience and tolerate anxiety, and passionate involvement in a task are examples of openness to affect states.

Two other more specific affective processes important in creativity are affective pleasure in challenge and affective pleasure in problem solving. The capacity to enjoy the excitement and tension in the challenge (Runco, 1994) and the capacity to take deep pleasure in problem solving (Amabile, 1990) are important in the creative process.

Finally, cognitive integration and modulation of affect is important in producing good and adaptive products. Cognitive control of affect is essential for the critical evaluation of ideas and products (Arieti, 1976; Kris, 1952).

There is a growing body of research that supports the link between play, affect, and creativity. Lieberman's (1977) work supports a relationship between affect in play and divergent thinking. She focused on the variable of playfulness which included the affective components of spontaneity and joy. She found that playful kindergarten children did better on divergent thinking tasks than nonplayful children. Singer and Singer (1990) reported that positive affect was related to imaginative play. Christie and Johnson (1983) also concluded that there is a relationship between playfulness and creativity. Singer and Singer (1981) found that preschoolers related as high imagination players showed significantly more themes of danger and power than children with low imagination.

In a series of studies by Russ and her colleagues using the Affect in Play Scale (APS), affect in play was found to be related to creativity. Russ and Grossman-McKee (1990) investigated the relationship among the APS and divergent thinking and primary process thinking on the Rorschach in 60 first and second grade children. As predicted, affective expression in play was significantly positively related to divergent thinking, as measured by the Alternate Uses Test. All major scores on the APS were significantly correlated with divergent thinking, with correlations ranging from 0.23 between comfort and divergent thinking to 0.42 between frequency of affective expression and divergent thinking. All correlations remained significant when IQ was partialed out; IQ had low correlations with the APS. The fact that intelligence did not relate to any of the play scores is consistent with the theoretical model for the development of the scale and is similar to the results of Singer (1973). Also, there were no gender differences in the pattern of correlations between the APS and divergent thinking.

The finding of a relationship between affect in play and divergent thinking (Russ & Grossman-McKee, 1990) was replicated by Russ and Peterson (1990; Russ, 1993) who used a larger sample of 121 first and second grade children. Once again, all of the APS scores were significantly and positively related to the Alternate Uses Test, independent of intelligence. Again, there were no gender differences in the correlations. Thus, with this replication, more confidence in the robustness of the relationship between affect in pretend play and creativity in young children is possible.

An important question about the APS is whether it is indeed measuring two separate dimensions of play—an affective dimension and a cognitive dimension—or is measuring one dimension an affect in fantasy dimension. The results of two separate factor analyses with the scale suggest two separate dimensions. Russ and Peterson (1990) carried out a principal component analysis with oblique rotation. It yielded two separate factors as the best solution. The first and dominant factor appeared to be a cognitive factor. Imagination, organization, quality of fantasy, and comfort loaded on this first factor. The second factor appeared to be an affective factor. Frequency of affective expression, variety of affect categories, and intensity of affect loaded on this second factor. Although separate factors, there was a significant amount of shared variance ($r = 0.76$), suggesting that the factors overlapped. A study by D'Angelo (1995) replicated the finding of two factors, one cognitive and one affective, with a sample of 95 first, second, and third grade children. This is an important finding because it lends support to the idea that cognitive expression and affective expression in play are related, but separate processes. Future studies with the play scale should use factor scores on the cognitive and affective factors as predictors of creativity.

Another interesting finding in D'Angelo's study (1995) was a significant relationship between the APS and Singer's (1973) imaginative play predisposition interview. Good players on the APS reported that they preferred activities that required using imagination.

A 1995 study (Russ, Robins, & Christiano, 1995), was a follow-up study of the first and second graders in the 1990 investigation of Russ and Peterson (1990). Fifth and sixth grade children were used for the follow-up. Thirty-one children agreed to participate in the follow-up study. This was a longitudinal study that explored the ability of the APS to predict creativity over a four year period (five years in some cases because the study took two years to complete). The major finding of the study was that quality of fantasy and imagination on the APS was predictive of divergent thinking over a four year period. However, the correlation between variety of affect and divergent thinking did not reach significance possibly due to the small sample size. In this study, an adapted version of the play task was administered to the older children. The instructions were altered so that the children were asked to put on a play with the puppets. The task was then scored based on the scoring criteria for the APS. Good stability was found in the dimensions being measured by the APS. For example, the size of the correlation between the two frequency of affect scores was $r = 0.33$, between the two variety of affect scores was $r = 0.38$, and between the two frequency of positive affect scores was $r = 0.51$. In general, the size of the correlations is respectable for a period of four and five years and lends support for enduring, stable constructs of affective expression in fantasy that are predictive over time of creative thinking. These findings also suggest an enduring quality to the affective and cognitive dimensions of the APS over a five year period.

5.09.5.4.3 Play and adjustment

There is some empirical work that suggest that play is related to adjustment. Singer and Singer (1990) concluded that imaginative play in children is related to academic adjustment and flexibility of thought. They also found that toddlers and preschoolers who engage in make-believe play are better adjusted across different situations. Burstein and Meichenbaum (1979) found that children who voluntarily played with stress-related toys prior to surgery demonstrated less distress and anxiety following surgery than children who avoided the toys. One might speculate that those children were accustomed to using play to deal with stress and problems. In a study of 4 to 11 year olds, Kenealy (1989) investigated strategies that children use when they are feeling depressed and found that 50% of the children's responses included play strategies. Also, indirectly, if play facilitates flexible problem solving, there is evidence that flexible problem solving, in turn, aids the coping process (Follick & Turk, 1978).

In a study of urban children from 4 to 5 years of age, Rosenberg (1984) found that the quality of fantasy play for children playing in dyads was positively related to measures of social competence and ego resilience (Block-Q sort). Frequency of positive themes and relationship themes in the play was also related to ego resilience and social competence. In general, children with behavior problems and attachment problems had fewer positive and negative themes in play, with the exception of diffuse hostility.

Grossman-McKee (1990) found, using the APS with first- and second-grade boys, that boys who expressed more affect in play had fewer pain complaints than boys with less affect in play. Good players were also less anxious on the State-Trait Anxiety Inventory for Children (Spielberger, 1973).

In a study of 7 to 9 year olds, Christiano and Russ (1996) found a positive relationship between play and coping, and a negative relationships between play and distress. Children who were "good" players on the APS implemented a greater number and variety of cognitive coping strategies (correlations ranging from 0.52 to 0.55) during an invasive dental procedure. In addition, good players reported less distress during the procedure than children who expressed less affect and fantasy in play.

5.09.5.4.4 Meta-analysis

Fisher (1992) conducted a meta-analysis of 46 studies in the play and child development area up to 1987. He investigated the impact of play on cognitive, affective-social, and linguistic processes. Both correlational and experimental studies were included. He found a mean effect size of 0.347 which is of low to modest size. He concluded that the major finding was that play does result in moderately large to noteworthy improvements on children's development. He made special note of the larger effect size for divergent thinking and perspective taking criteria.

In summary, play helps the child to:

(i) Practice with the free flow of associations that is important in divergent thinking.

(ii) Practice with symbol substitution, recombining of ideas, and manipulation of object representations. These processes are important in developing insight abilities.

(iii) Express and experience both positive and negative affect.

(iv) Express and think about affect themes in fantasy. Emotional content and primary process content is permitted to surface and be expressed through play. Over time, the child develops a variety of memories and associations. This broad repertoire of associations helps in creative problem solving. Fein's (1987) affective symbol system could be developed in this way.

(v) Resolve conflicts and master the traumas of daily life.

(vi) Develop cognitive structure that could help the child contain and modulate affect.

(vii) Practice with a variety of coping skills and interpersonal behavior important in everyday life.

5.09.6 RESEARCH FINDINGS

Russ (1995) reviewed the current state of play therapy research. In that review, a distinction between psychotherapy outcome research in general and play intervention research was made. The broad category of psychotherapy outcome research makes sense because most of those studies did not focus specifically on play. Play is frequently embedded in the therapy intervention. Therefore, the results of those studies provide an important context in which to think about play.

5.09.6.1 Psychotherapy Outcome Research

In general, the early reviews of child therapy outcome studies concluded that there was little or no support for child therapy. More recent work has concluded that there is support for the effectiveness of child psychotherapy if the research is well designed.

A classic early review by Levitt (1957) concluded that the mean improvement rate for children was not significantly better than the baseline improvement rate of 72.5% for untreated controls. In later work, in a review of 47 reports of outcome studies, Levitt (1963, 1971) concluded that approximately two-thirds of treated children in therapy were improved, but again treated children were no better off than untreated controls. Levitt's conclusions were taken seriously by the field of child psychotherapy.

A number of researchers responded to Levitt's conclusions (Halpern, 1968; Heinicke & Goldman, 1960; Hood-Williams, 1960). One of the major methodological issues was that so many of the untreated controls were defectors from treatment. Defectors were children who were evaluated and recommended for treatment but who had not entered treatment. Therefore, there may have been a number of confounding variables operating here to account for the results.

Barrett, Hanpe, and Miller (1978) and Hartmann, Roger, and Gelsand (1977) took a closer look at Levitt's reviews and at the research literature in general. They concluded that there was still no solid empirical evidence for the effectiveness of psychotherapy. Barrett et al. (1978) stated that the global nature of the research was a major problem and concluded that most of the research studies were not specific enough or focused enough to enable research questions to be answered. There was too much of a mix of populations, therapeutic approaches, and interventions in these studies. Often, the outcome measures were unrefined or nonexistent. This led to their often quoted conclusion that the question in psychotherapy research should not be "Does psychotherapy work?" but rather "Which set of procedures is effective when applied to what kinds of patients with which sets of problems and practiced by which sorts of therapists?" (p. 428)

A number of other methodological issues important for research in the child therapy area have been identified: namely, the importance of classification according to developmental level (Heinicke & Strassman, 1975); controlling for maturational effects (Koocher & Broskowski, 1977); the need for homogeneous treatment groups (Achenbach, 1978; Hartmann et al., 1977); the need to control for sex and age variables (Cass & Thomas, 1979); and the need for adequate outcome measures given at appropriate intervals (Kazdin, 1990, 1993b).

The field of child therapy research has followed these research guidelines and the research studies have become more focused and methodologically sophisticated. In addition, the technique of meta-analysis has enabled the field to arrive at a more systematic evaluation of outcome studies. As Weisz and Weiss (1993) noted, meta-analysis is a technique that enables the pooling and statistical summarizing of the results of outcome studies. The effect size (ES) is the statistical summary of the treatment efficacy across studies. Use of this systematic procedure helps avoid reviewer subjectivity in coming to conclusions.

Weisz and Weiss (1993) reviewed the major meta-analytic studies in the field of child psychotherapy. Casey and Berman (1985) calculated the effect of psychotherapy across 64 studies and found a mean effect size of 0.71. A slightly higher effect size of 0.79 was found by

Weisz, Weiss, Alicke, and Klotz (1987) in a review of 163 treatment-control comparisons. Both studies concluded that the average treated child functioned better after treatment than three-fourths of the untreated controls. In the Casey and Berman review, effect sizes did not differ as a function of whether play was used. In a meta-analyses by Kazdin, Bass, Ayers, and Rodgers (1990), for 64 studies involving treatment vs. no-treatment comparisons, the mean effect size was 0.88. Weisz and Weiss (1993) concluded that "the mean effect sizes reported in child meta-analyses are quite comparable to those of adult meta-analyses and that findings in both categories point to quite positive effects of therapy" (p. 46).

As Kazdin (1990) has pointed out, the results of these meta-analyses have contributed to the field in that they offer evidence that psychotherapy is more effective than no treatment with children. This conclusion is more encouraging than the conclusions based on the reviews in the 1950s, 1960s, and 1970s. Although these child therapy outcome studies did not focus on play *per se*, one might infer that play is an effective form of treatment since it is so frequently part of the therapy process. The Casey and Berman (1985) review found no difference in effectiveness between those studies that used play and those that did not.

Weisz and Weiss (1989, 1993) pointed out that most of the research studies in the meta-analyses involved controlled laboratory interventions. In many of these studies children were recruited for treatment and were not clinic-referred; samples were homogeneous; there was a focal problem; therapy focused on the target problem; therapists were trained in the specific treatment approaches to be used; and the therapy relied primarily on those techniques. In essence, this was good research that followed many of the methodological guidelines for adequate research design. On the other hand, Weisz and Weiss (1993) cautioned that the evidence for the effectiveness of psychotherapy is based on studies that are not typical of conventional clinical practice. Thus the findings may not be generalizable to real clinical work.

The results of the meta-analysis point to the need for specificity and precision. Weisz and Weiss (1993) concluded that the studies that showed positive results tended to "zoom in" on a specific problem with careful planning of the intervention. Freedheim and Russ (1983, 1992) stated that we needed to become very specific and ask "Which specific interventions affect which specific cognitive, personality, and affective processes? How are these processes related to behavior and practical clinical criteria?" (1983, p. 988). Shirk and Russell (1996) also call for the targeting of specific cognitive, affective, and interpersonal processes in child therapy.

In a review of the play therapy research, Phillips (1985) also called for a systematic program of research with well-controlled studies. He concluded that the play therapy research that found positive results were those studies of a cognitive-behavioral nature that were carefully designed. Phillips speculated that the specificity of treatment goals and focused methods of the cognitive-behavioral studies partially account for the positive results. He recommended that all forms of play therapy be investigated with the precision of the cognitive-behavioral studies. In general there are not many play therapy studies in the literature and little exploration of variables that leads to change (Faust & Burns, 1991).

It should be relatively easy to apply the principles of specificity and focus to the play area. Play interventions and the cognitive and affective processes that they effect can be broken down into discrete units in controlled conditions. The large body of research in the play and child development literature offers a wealth of ideas and research lines that could be followed.

5.09.6.2 Play Intervention Research

As Russ has reviewed (1995), studies exist that have investigated the effect of play on specific types of problems and in specific populations. These studies are a good bridge between empirical laboratory studies of play and specific processes, like creativity, and more global clinical practice outcome studies. These studies have been labeled play intervention rather than play therapy, because the focus is highly specific. Usually, they involve only a few sessions with no emphasis on forming a "relationship" with a therapist. On the other hand, these studies differ from specific process research in child development in that they are problem focused and are not as fine-tuned as they would be in laboratory research. These play intervention research studies seem to fit some of Weisz and Weiss's (1993) criteria by including children who are not clinic-referred, by having homogeneous samples, and by having a focal problem that the therapy focused on.

Phillips (1985) reviewed two studies that would fall into this play intervention research category. Both involved the use of puppet play to reduce anxiety in children facing surgery. Johnson and Stockdale (1975) measured Palmer Sweat Index level before and after surgery. Puppet play in this study involved playing out the surgery. Johnson and Stockdale found less anxiety for the puppet-play group before and after surgery. The one exception was immediately before surgery, when the increased information may have elevated their anxiety. Cassell (1965) used puppets with children undergoing cardiac catheterization and found that anxiety was reduced before surgery for the puppet-play group compared with the no treatment control. There were no differences after surgery. The treatment group was less disturbed during the cardiac catheterization and expressed more willingness to return to the hospital for further treatment. Rae, Worchel, Upchurch, Sanner, and Daniel (1989) investigated the effects of play on the adjustment of 46 children hospitalized for acute illness. Children were randomly assigned to one of four experimental groups:

(i) Therapeutic play condition in which the child was encouraged to play with medical and nonmedical materials. Verbal support, reflection, and interpretation of feelings were expressed by the research assistant.

(ii) A diversionary play condition in which children were allowed to play with toys but fantasy play was discouraged. The toys provided did not facilitate fantasy, nor did the research assistant.

(iii) A verbally oriented support condition in which children were encouraged to talk about feelings and anxieties. The research assistant was directive in bringing up related topics and would ask about procedures.

(iv) A control condition in which the research assistant had no contact with the child.

All treatment conditions consisted of two 30-minute sessions. The main result of this study was that children in the therapeutic play group showed significantly more reduction in self-reported hospital-related fears than children in the other three groups. There were no differences among the groups for parent ratings.

Another specific problem area that lends itself to focused intervention research is that of separation anxiety. In an excellent example of a well-designed play intervention study, Milos and Reiss (1982) used play therapy for preschoolers who were dealing with separation anxiety. They identified 64 children who were rated as high-separation-anxious children by their teachers. The children were randomly assigned to one of four groups. Three play groups were theme related: the free-play group had appropriate toys; the directed-play group had the scene set with a mother doll bringing the child to school; the modeling group had the experimenter playing out a separation scene. A control group also used play with toys irrelevant to separation themes (blocks, puzzles, crayons). All children received three individual 10 minute play sessions on different days. Quality of play was rated. The results showed that all three thematic play conditions were effective in reducing anxiety around separation themes when compared to the control group. An interesting finding was that, when the free-play and directed-play groups were combined, the quality of play ratings were significantly negatively related ($r = -0.37$) to a posttest anxiety measure. High-quality play was defined as play that showed more separation themes and attempts to resolve conflicts. One might speculate that the children who were already good players used the intervention to master their separation anxiety. Milos and Reiss concluded that their results support the underlying assumption of play therapy, that play can reduce anxiety associated with psychological problems. The finding that quality of play was related to effectiveness of the intervention is consistent with the finding of Dansky (1980); that free play facilitated creativity only for those children who used make-believe well.

A well-designed study by Barnett (1984) also looked at separation anxiety and expanded upon work by Barnett and Storn (1981) in which free play was found to reduce distress in children following a conflict situation. In the 1984 study, a natural stressor, the first day of school, was used. Seventy-four preschool children were observed separating from their mothers and were rated anxious or nonanxious. These two groups were further divided into play or no play conditions. The play condition was a free play condition. The no-play condition was a story-listening condition. For half of the play condition, play was solitary. For the other half, peers were present. The story condition was also split into solitary and peers present segments. Play was rated by observers and categorized in terms of types of play. Play significantly reduced anxiety in the high-anxious group. Anxiety was measured by the Palmer Sweat Index. There was no effect for low-anxious children. For the anxious children, solitary play was best in reducing anxiety. High-anxious children spent more time in fantasy play than did low-anxious children, who showed more functional and manipulative play. They engaged more in fantasy play when no other children were present. Barnett interpreted these results to mean that play was used to cope with a distressing situation. The findings supported her idea that it is not social play that is essential to conflict resolution, but rather imaginative play qualities that the child introduces into playful behavior. Actually, the presence of peers increased anxiety in the high-anxious group.

These play intervention studies are a few examples of the kind of studies that tell us about how play can be helpful in dealing with specific problems. The results of these studies suggest that play helps children deal with fears and reduce anxiety and that something about play itself is important and serves as a vehicle for change. The play experience is separate from the experience of a supportive and empathic adult. Results also suggest that children who are already good players are more able to use play opportunities to resolve problems when these opportunities arise. Teaching children good play skills would provide children with a resource for future coping.

5.09.7 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

The main tasks of the next 10 years, up to 2007, in the play therapy area are to: (i) apply the body of knowledge from the play and child development research literature to play intervention and (ii) carry out well-designed play intervention studies with specific populations of children. These are major tasks that require a coordinated set of research studies and programs.

Play therapy itself will become more focused with specific populations of children. This is already occurring. For example, Chethik (1989) described "focal therapy" as therapy that focuses on a specific problem and is of short duration. Play is frequently used in this therapy. Focal stress events such as death in the family, divorce, hospitalization, or illness are examples of problems that would be dealt with Chethik stated that focal therapy is effective when the child has accomplished normal developmental tasks before the stressful event occurs.

Mann and McDermott (1983) discussed play therapy with abused and neglected children. Often, these children must be taught how to play. Gil (1991) provided a good review and discussion of post-traumatic play. An active approach in which she brings in outside material and events is often necessary. Gil stressed the importance of the therapist being an active participant in the play with abused children. If the child is a disorganized player, the therapist must focus the play choices in a relatively restricted setting. If the child has been understimulated and cannot play well, then the therapist should bring in appropriate toys and model play. For many abused children, the therapist needs to actively facilitate self-expression by such techniques as presenting the child with cartoon figures in different situations with the child filling in their words or pulling secrets from a "secrets" bag. For many children post-traumatic play is repetitive, devoid of pleasure, and can remain fixed (Gil, 1991). Gil attempts to intervene in this repetitive play by making verbal statements, having the child take a specific role, or encouraging the child to differentiate between the traumatic event and current reality in terms of safety and what has been learned. Gil stated that the goal of interrupting the play is to generate alternatives that can lead to a sense of control, help feelings be expressed and orient the child toward the future. Gil's work illustrates how specific play techniques need to be developed for specific populations.

D. Singer (1993) described the active use of modeling, imagery techniques, and teaching adaptive skills within the play therapy context. Along with traditional play therapy techniques, she utilizes imagery techniques that help the child visualize people, conflicts, and resolutions. She also incorporates behavior modification techniques that reinforce positive behavior and lead to self-reward. Knell's (1993) cognitive-behavior play therapy and Bodiford-McNeil et al's. (1996) short-term play therapy are examples of focused therapies with a very active therapist.

Play therapy will also need to integrate a variety of theoretical approaches and techniques. As it becomes evident that a variety of theoretical approaches can use play in therapy, a larger variety of play techniques will become available. If we can combine this increased repertoire of play techniques with good research then the field of play therapy will move forward.

Short-term play intervention modules may evolve as effective interventions. Kazdin (1993a) discussed the possibility of having different modules of intervention for different problems. This concept would work for the play therapy area. 6–12 week play modules could be developed for different types of problems. Bodiford-McNeil et al. (1996) are already doing this with disruptive children. Children who have experienced trauma might benefit from the opportunity to play-out the issues in a focused approach. Constricted children could benefit from play modules directed at increasing affective expression. Play assessment could identify what types of play experiences could be most beneficial.

Research programs in play therapy need to be at both the micro and macro levels. First, laboratory research on play and cognitive and affective processes must continue. Concurrent, longitudinal, and experimental studies on specific dimensions of play and specific cognitive, affective, and personality processes need to be carried out in a systematic fashion. We especially need to identify what dimensions of play most relate to specific processes. For example, does affect expression increase divergent thinking? Does positive affect have a different effect than negative affect? Are there different effects with different age groups and different populations of children?

Second research needs to be carried out with focused play interventions. Russ (1995) outlined different types of play intervention research.

(i) Specific Play Interventions with Specific Populations and Specific Situations. The Barnett (1984) study with children who were experiencing the first day of school is a good example of this type of study. There are a variety of natural stressors that could be used to investigate play intervention. Divorce, natural disasters, dental visits, presurgery, and loss of a parent are all situations in which play intervention is used. We need to develop an empirical base for play intervention in these situations.

(ii) Refining Specific Play Techniques. The general question of what kinds of intervention by the therapist best facilitate play needs to be studied empirically. There are many guidelines in the clinical literature about how to facilitate play, but few are based on empirical work. How do we best encourage affect in play? When is modeling more effective than a less directive approach.? When is it less effective? For example, Gil (1991) pointed out that it is frequently important with sexually abused children to be nondirective, so that the child does not feel intruded upon. What kinds of intervention most enhance the working-through process and conflict resolution? These kinds of research questions can be posed in well-controlled experimental studies and in psychotherapy-process research.

Third, dissemination of research results should inform clinical practice and prevention programs. For example, guidelines about how to best facilitate affective expression in play could be better incorporated into play therapy. Treatment manuals using these guidelines can and should be developed.

In the future, large scale play training and prevention programs could reach large numbers of children. Play centers in schools might be one way to reach children (Russ, 1993). Smilanksy (1968) has demonstrated that play skills can effectively be taught to children by teachers in a relatively short time. More training groups for parents on how to help children play at home, perhaps through Head Start programs would also be worthwhile. Play preparation for hospital procedures might increase. Teaching children to use play as a major coping resource might be a trend of the future.

One thing is certain, children will continue to play. Above all else, it is fun and reinforcing. Children naturally use play for a variety of purposes. It is up to us to learn how children use play and to help them use play more effectively.

5.10.1 THE PSYCHOANALYTIC ROOTS OF PSYCHODYNAMIC THERAPY

5.10.1.1 Definition of Psychodynamic Therapy

The term psychodynamic therapy covers psychotherapeutic approaches which share the assumption that psychological disorders are rooted in conflicting motivational states, often unconscious, which the individual responds to with a variety of habitual strategies (psychiatric symptoms). Most psychodynamic formulations specify that such conflict is "intrapsychic" (e.g., Brenner, 1982); others include interpersonal conflict, but even there the implication remains that conflict occurs between an internal state and the internal meaning of an external situation (Sullivan, 1953). Psychological intervention is conceived of as assisting individuals to use and develop their inherent capacities for understanding, learning, and emotional responsiveness, in response to the therapeutic relationship and especially the therapist's interpretations of the patient's motivations and strategies, to arrive at more adaptive resolutions. There is no fixed set of techniques to be used in this task, and different therapeutic orientations emphasize different, although substantively overlapping, procedures. Distinctions between types of psychodynamic therapy can be made along several lines; for example, we distinguish psychodynamic individual therapy from group therapy (Rose, 1972) or family approaches (Selvini Palazzoli, Boscolo, Cecchin, & Prata, 1978), expressive from supportive techniques (Luborsky, 1984), Freudian from Kleinian psychoanalytic orientation (King & Steiner, 1991), and therapies may be distinguished according to the relative emphasis of adjuncts such as play (Schaefer & Cangelosi, 1993), art (Simon, 1992), or drama (Johnson, 1982).

This chapter will principally concern itself with individual psychodynamic psychotherapy, using the verbal or play technique.

5.10.1.2 Historical Overview of Psychodynamic Developmental Theory

We will briefly summarize psychoanalytic theories of development, which are considered in more depth Chapter 14, Volume 1.

Freud was the first to give meaning to mental disorder by linking it to childhood experiences (S. Freud & Breuer, 1895), and to the vicissitudes of the developmental process (S. Freud, 1900). One of S. Freud's significant contributions was undoubtedly the recognition of childhood sexuality (S. Freud, 1905). Few, inside or outside psychoanalysis, now doubt that children experience sexual feelings from the earliest days (Green, 1985). S. Freud's discoveries radically altered our perception of the child from one of somewhat idealized naïveté and innocence to that of a human being struggling to adapt his biological, constitutional characteristics to social circumstances. S. Freud's image of the child is of a person in turmoil (S. Freud, 1933), struggling to achieve control over their biological needs, and make them acceptable to society at large through the microcosm of their family (S. Freud, 1930).

Ego psychologists balanced this view by focusing on the evolution of children's adaptive capacities (Hartmann, 1939), which they bring to bear on the struggle with their biological needs. Hartmann's model (Hartmann, 1939) attempted to take a wider view of the developmental process, to link drives and ego functions, and show how negative interpersonal experiences beyond the expectable range could jeopardize evolution of the psychic structures essential to adaptation. He also showed that the reactivation of earlier structures (regression) was the most important component of psychopathology. Hartmann (1995, p. 221) was also among the first to point to the complexity of the developmental process, stating that the reasons for the persistence of particular behavior are likely to be different from the reasons for the original appearance of the behavior, earlier in development. Among the great contributions of ego psychologists are the identification of the ubiquitous nature of intrapsychic conflict throughout development (Brenner, 1982), and the recognition that genetic endowment, as well as interpersonal experiences, may be critical in determining the child's developmental path. The latter idea has echoes in the epidemiological concept of resilience (Garmezy & Masten, 1991; Rutter & Quinton, 1984).

Child analysts (e.g., Fraiberg, 1969, 1980; Anna Freud, 1965) taught us that symptomatology is not a fixed formation, but rather a dynamic entity superimposed upon, and intertwined with, an underlying developmental process. A. Freud's study of symptomatic and asymptomatic children under great social stress led her to formulate a relatively comprehensive developmental theory, where the child's emotional maturity could be identified independently of diagnosable pathology. Particularly in her early work in the war nurseries (A. Freud, 1941–1945), she identified many of the characteristics which later research linked to the so-called resilient child (Rutter, 1990). For example, her observations spoke eloquently of the importance of social support which children could give one another in situations of extreme stress (concentration camps), which could ensure their physical and psychological survival. More recent research on youngsters experiencing trauma has confirmed her assertion of the protective power of sound social support (Garmezy, 1983; MacFarlane, 1987; O'Grady & Metz, 1987; Werner, 1989). Anna Freud's work stayed so close to the external reality of the child that it lent itself to a number of important applications (Goldstein, Freud, & Solnit, 1973, 1979).

A. Freud was also a pioneer in identifying the importance of an equilibrium between developmental processes (A. Freud, 1965). Her work is particularly relevant in explaining why children, deprived of certain capacities by environment or constitution, appear to be at greater risk of psychological disturbance. Epidemiological studies substantiate that harmonious development is threatened by constitutionally acquired weaknesses. Anna Freud's work is remarkable in that she was the first psychoanalyst to place the process and mechanisms of development at the center-stage of psychoanalytic thinking. Her approach is truly one of developmental psychopathology, insofar as she defines abnormal functioning in terms of its deviation from normal development, while at the same time using the understanding gained from clinical cases to illuminate us about the ontogenetic progress of the normal child (Cicchetti, 1990a; Sroufe, 1990).

Mahler (1968) drew attention to the paradox of self-development, that a separate identity implies the giving up of a highly gratifying closeness with the caregiver. Her observations of the "ambitendency" of children in their second year of life were helpful in understanding individuals with chronic problems of consolidating their individuality. Mahler's framework highlights the importance of the caregiver in facilitating separation, and helps explain the difficulties experienced by children whose parents fail to perform a social referencing function for the child, evaluating for them the realistic danger associated with unfamiliar environments (Feinman, 1991; Hornik & Gunnar, 1988). A traumatized, troubled parent may hinder rather than help a child's adaptation (Terr, 1983). An abusive parent may altogether inhibit the process of social referencing (Cicchetti, 1990b; Hesse & Cicchetti, 1982). The pathogenic potential of the withdrawing object, when confronted with the child's wish for separateness, was further elaborated by Masterson (1972) and Rinsley (1977), and is helpful in accounting for the transgenerational aspects of psychological disturbance (see Baron, Gruen, & Asnis, 1985; Links, Steiner, & Huxley, 1988; Loranger, Oldham, & Tullis, 1982).

Sandler's development of Anna Freud's and Jacobson's work (e.g., Sandler & Rosenblatt, 1962) is a coherent integration of the developmental perspective with psychoanalytic theory. His comprehensive psychoanalytic model has permitted developmental researchers (Emde, 1983, 1988a, 1988b; Stern, 1985) to integrate their findings with a psychoanalytic formulation, which clinicians have also been able to use. At the core of Sandler's formulation lies the representational structure which contains both reality and distortion, and is the driving force of psychic life. A further important component of his model is the notion of the background of safety (Sandler, 1987), closely tied to Bowlby's concept of secure attachment.

Klein and her followers constructed a developmental model (Klein, Heimann, Isaacs, & Riviere, 1946) which at the time met great opposition because of the apparently extravagant assumptions these workers were ready to make about the cognitive capacities of infants. However, developmental research appears to be consistent with many of Klein's claims concerning the perception of causality (Bower, 1989) and causal reasoning (Golinkoff, Hardig, Carlson, & Sexton, 1984). Kleinian developmental concepts have become popular because they provide helpful descriptions of the clinical interaction between both child and adult patient and analyst. For example, projective identification depicts the close control that primitive mental function can exert over the analyst's mind. Modern Kleinian psychoanalysts (Bion, 1962, 1963; Rosenfeld, 1971) have been particularly helpful in underscoring the potential impact of emotional conflict on the development of cognitive capacities.

The early relationship with the caregiver emerged as a critical aspect of development from studies of severe character disorders by psychoanalysts in Britain. Fairbairn's focus on the individual's need for the other (Fairbairn, 1952) helped shift psychoanalytic attention from structure to content, and profoundly influenced both British and North American psychoanalytic thinking. As a consequence of this development, the self as a central part of the psychoanalytic model emerged in the work of Balint (1937, 1968) and Winnicott (1971). The concept of the caretaker or false self, as a defensive structure created to master trauma in a context of total dependency, has become an essential developmental construct. Winnicott's (1965) notions of primary maternal preoccupation, transitional phenomena, the holding environment, and the mirroring function of the caregiver, provided a clear research focus for developmentalists interested in individual differences in the development of self-structure. The significance of the parent–child relationship is consistently borne out by developmental studies of psychopathology. These studies in many respects support Winnicott's assertions concerning the traumatic effects of early maternal failure, particularly maternal depression (see Cummings & Davis, 1994), and the importance of maternal sensitivity for the establishment of a secure relationship (Ainsworth, Blehar, Waters, & Wall, 1978; Belsky, Rovine, & Taylor, 1984; Bus & Van IJzendoorn, 1992; Grossmann, Spangler, Suess, & Unzer, 1985).

The central developmental idea of Kohut's formulation (Kohut, 1971, 1977, 1984) was the need for an understanding caretaker to counteract the infant's sense of helplessness in face of biological striving for mastery. Kohut emphasizes the need for such understanding objects throughout life and these notions are consistent with accumulating evidence for the powerful protective influence of social support identified across a wide range of epidemiological investigations (Brown & Harris, 1978; Brown, Harris, & Bifulco, 1986). The mirroring object becomes a "self-object," and the need for empathy drives development, which culminates in the attainment of a cohesive self. Drive theory becomes secondary to self-theory, in that the failure to attain an integrated self-structure both leaves room for, and in itself generates, both aggression and isolated sexual fixation. However, the self remains problematic as a construct; in Kohut's model, it is both the person (the patient) and the agent which is assumed to drive the person (Stolorow, Brandchaft, & Atwood, 1987). However, Kohut's descriptions of the narcissistic personality have been powerful and influential examples of the use of developmental theory in psychoanalytic understanding. Kohut's focus on self-esteem has been shown by empirical research to be appropriate and somewhat lacking in previous psychoanalytic formulations.

Kernberg's systematic integration of structural theory and object relations theory (Kernberg, 1976, 1982, 1987) is probably the most frequently used psychoanalytic model, particularly in relation to personality disorders. His model of psychopathology is developmental, in the sense that personality disturbance is seen to reflect the limited capacities of the young child to address intrapsychic conflict. Neurotic object relations show much less defensive disintegration of the representation of self and objects into libidinally invested part–object relations. In personality disorder, part–object relations are formed under the impact of diffuse, overwhelming emotional states, ecstatic, or of an equally overwhelming but terrifying and painful nature which signals the activation of aggressive or persecutory relations between self and object. Kernberg's models are particularly useful because of their level of detail and his determination to operationalize his ideas far more than has been traditional in psychoanalytic writing.

Bowlby's (1969, 1973, 1980) work on separation and loss also focused developmentalists' attention on the importance of the security (safety and predictability) of the earliest relationships. His cognitive-systems model of the internalization of interpersonal relationships (internal working models), consistent with object relations theory (Fairbairn, 1952; Kernberg, 1975) and elaborated by other attachment theorists (Bretherton, 1985; Crittenden, 1990; Main, Kaplan, & Cassidy, 1985), has been particularly influential.

According to Bowlby, the child develops expectations regarding a caregiver's behavior and the child's own behavior.These expectations are based on the child's understanding of experiences of previous interaction, and are helpful in organizing the child's behavior with the attachment figure and (through a process of extrapolation with others) with others. The concept has had very broad application. Bowlby's developmental model highlights the transgenerational nature of internal working models: our view of ourselves depends upon the working model of relationships which characterized our caregivers. Empirical research which places this intergenerational model under systematic scrutiny has begun, and the robustness of the findings is encouraging. There is an accumulating body of data which confirms that there is some kind of intergenerational transmission of attachment security and insecurity (see review by van IJzendoorn, 1995) and that parental mental representations pertinent to this process may be assessed before the birth of the first child (e.g., Fonagy, Steele, Moran, Steele, & Higgitt, 1991a; Fonagy, Steele, & Steele, 1991b; Ward & Carlson, 1995).

Stern's (1985) work represents a milestone in psychoanalytic theories of development. His work is remarkable within psychoanalysis for being normative rather than pathomorphic, and prospective rather than retrospective. His focus is the reorganization of subjective perspectives on self and other as these occur with the emergence of new maturational capacities. He is perhaps closest to Sandler in his psychoanalytic model of the mind, but his formulation of object relations also has much in common with those of Bowlby and Kernberg.

5.10.1.3 Evolution of the Psychodynamic Technique with Children

Specific therapeutic techniques which could help psychoanalysts in addressing psychiatric problems of childhood did not appear until the 1920s. Application of the insights gained from psychoanalytic treatment of adults to the treatment of children was prepared by Freud's observations concerning the psychology of young children. The most notable ones include Anna Freud's wishful dream for strawberries (S. Freud, 1900), and his grandson's separation game (S. Freud, 1920). Best known is S. Freud's case study of Hans (S. Freud, 1909), a five-year-old with an animal phobia, whose treatment by his physician father was supervised by S. Freud. All these observations were used by S. Freud principally to confirm his assumptions about infantile instinctual life through the direct observation of children and to prevent him (and other adult psychoanalysts) from making false developmental assumptions (S. Freud, 1926, p. 215).

Hug-Helmuth (1920, 1921) was the first clinician to introduce play therapy into the psychoanalyst's armamentarium. Her pioneering work, which is now largely forgotten, combined an insight-oriented technique, focused primarily on the child's unconscious sexual fantasies, with a powerful developmental perspective, whereby she saw the young person as needing to be "strengthened" in the mental capacities needed for his developmental tasks. This latter emphasis has echoes in present-day cognitive therapy and psychoanalytic approaches. Up to that point, most analysts shared the Hungarian analyst Ferenczi's skepticism about offering psychoanalysis to children who do not wish to be analyzed as they solely wish to play (see Group for the Advancement of Psychiatry, 1982, for a comprehensive history of the field).

The other great pioneers of the field, A. Freud (1946) and Klein (1932), independently (but frequently with reference to one another), evolved techniques to enable clinicians to take a psychoanalytic therapeutic approach to children. Klein's approach, working under the influence of Abraham, a Berlin based psychoanalyst, was to regard children's play as essentially the same as the free association of adults, motivated by unconscious fantasy activated principally by the relationship with the analyst and requiring verbalization (interpretation) if the child's anxiety was to be adequately addressed. Interpretation of the child's deep anxieties concerning destructive and sadistic impulses was the principal focus of child analytic work. She advocated that therapists establish an interpretative relationship, even with preschool children, from the beginning. The emphasis placed on the relationship with the analyst meant that work with parents and other adults in the child's life (e.g., teachers) was not seen as central.

Direct interpretation of the projective processes was seen by Klein as critical. In *Notes on some schizoid mechanisms* (Klein, 1946) and in her paper on *The origins of transference* (Klein, 1952), Klein discussed the importance of the common childhood unconscious fantasy of placing part of the self into another person and perceiving unwanted qualities in them rather than oneself in order to relieve oneself of unwanted feelings (such as greed or envy). This form of fragmentation of the sense of self was regarded by her as part of normal infantile development but when persisting beyond infancy was the cause of pathology and the key focus for interpretation. She assumed that while projective identification was distressing to the child it was also helpful in creating the fantasy, not only that others were the "containers" of the child's own unwelcome traits, but also that (as these unattractive attributes still partly belonged to the self) the child could control the other person (object). The clinician's understanding was enriched by the assumption that a child's perception of the clinician gave clues about conflictual aspects of the child's experience of his self. Bion (1959) showed how such projective experiences could be expected to have an impact on "the container" and how the capacity of that individual to "metabolize" (understand and accept) the projection may be critical in development as well as in the success of therapy. Thus, the therapist's subjective experience (countertransference) could be a clue to the child's unconscious fantasies, and her capacity to understand and tolerate these, the key component of successful treatment.

Modern Kleinians (e.g., DeFolch, 1988; O'Shaughnessy, 1988) have, to some degree, modified the classical Kleinian position; early interpretations of assumed deeply unconscious material are less frequently offered, and there is greater attention to defensive qualities of many manifestations of the child's nonconscious processes. The immediate interaction with the analyst, however, remains the core focus of therapeutic work, and the underlying conceptualization remains based on the notion of fragmentation of the self-representational structure which may be undone through verbalization and interpretation. The countertransference experience of the therapist is the central guide.

Drawing on the work of Klein, Winnicott (1965, 1971) reinforced Klein's emphasis on the influence of early life on childhood pathology while introducing additional techniques into child analysis. For example, specific drawing techniques were used, while Winnicott also emphasized nonverbal aspects of the therapist's stance, in particular the importance of a "holding" environment and the central role of play. One of his major contributions was the concept of a transitional area between self and object where the subjective object and the truly objective object are simultaneously recognized (Winnicott, 1971). This insight was critical in developing an appreciation of the interpersonal nature of therapeutic interaction in child analysis (Altman, 1994).

By contrast, A. Freud's approach placed more emphasis on the child's developmental struggle with adaptation to a social as well as an intrapsychic environment. Her training as a nursery school teacher led her to be very concerned with the child's actual external circumstances, as well as their unconscious world. She made fewer assumptions concerning the meaning of the child's play, approached therapeutic work far more gradually, recommended working in collaboration with parents and teachers (particularly in communicating understanding derived from the therapy), and focused far more on the complications and conflicts arising from the child's libidinal (sexual) impulses than on innate aggression. Her focus was on the child's wish to protect their fragile internal world from conflict by adopting psychological strategies (mechanisms of defense, A. Freud, 1936) such as denial, repression, or identification with the aggressor. The focus of her technique therefore was the interpretation of defenses and through this, the anxieties which motivated them.

The Anna Freudian approach to child analysis invariably takes into consideration the limitations upon the child's "ego functioning" imposed by development, and has as its primary focus the support of the development of the ego and the restoration of the child to a normal developmental path. Pine (1985) stressed that the analyst, like the parent, creates a supportive environment for the child's incompletely developed ego. He saw such techniques as mutative in their own right and considered interpretations in the context of support to be qualitatively different from interpretations in the context of abstinence, as is recommended by Kleinian child analysts. The pressure for the analyst to be an active and "real" participant in the therapeutic situation has thus been growing apace (see also Altman, 1992; Warshaw, 1992). However, many of these reconceptualizations lack coherent theoretical rationale and specific technical recommendations as to how departures from abstinence may be put to good therapeutic effect.

Anna Freudian child psychoanalysis became popular as a treatment in the US in the first half of the twentieth century, and was systematically described by A. Freud and her colleagues (Sandler, Kennedy, & Tyson, 1980); it has also influenced many forms of psychodynamic treatment of children and families. Individual child psychodynamic psychotherapy, based on these principles, has been shown to be a form of treatment frequently used and highly regarded among child psychiatrists and psychologists in the US (Kazdin, Bass, Siegel, & Thomas, 1990a). In the UK, as well as in Latin America, Klein's model proved to be more popular.

5.10.1.4 The Common Assumptions of Psychodynamic Therapy

Psychodynamic child psychotherapy shares many of its basic assumptions with adult psychoanalysis. Numerous summaries of these are available (see Chapter 14, Volume 1, Fonagy, Target, Steele, & Gerber, 1995; Gabbard, 1994, 1995; Kernberg, 1995; Summers, 1994, for more comprehensive accounts) and here we shall only provide a brief overview.

Psychodynamically oriented child therapists assume that mental disturbance may be usefully studied at the level of *psychological causation*, that the representation of past experience, its interpretation, and meaning, largely unconscious, determine the child's reaction to his external world and capacity to adapt to it. The emphasis on psychic causation does not imply either a lack of respect for or inattention to other levels of analysis of childhood psychiatric problems such as the biological, the family, or broader social factors. Nevertheless, psychiatric problems, whether at the root genetic, constitutional, or socially caused, are seen by the psychodynamically oriented child clinician also as the meaningful consequence of the child's unconscious beliefs, thoughts, and feelings, and therefore, potentially accessible in psychotherapy.

Complex unconscious mental processes are assumed to be responsible for the content of thinking and behavior. In particular, unconscious fantasies associated with wishes for instinctual pleasure or safety (Sandler, 1987) motivate the child's behavior, affect regulation, and the ability to cope with the social environment.

The experience of the self with others is internalized and leads to representational structures of interpersonal interactions which, at the simplest level, determine expectations of others and more elaborately determine the "shape" of self and other representations, and the nature of the internal world of the child. This general idea is formulated somewhat differently by psychodynamic clinicians from different traditions. Bowlby's concept of "internal working models" of self–other relationships based on the infant–mother relationship is perhaps the closest to formulations from other areas of clinical psychology (Bowlby, 1973, 1980). In essence, all so-called "object-relations" theories posit that the emotional life of the child (and adult) is organized around mental representations, however partial, of the self in relation to an important figure, imbued with a specific affect (e.g., Kernberg, 1976).

It is assumed that psychic conflict is ubiquitous and a cause of suffering (or a felt lack of safety) (Brenner, 1982). Adverse environments of childhood may create intrapsychic conflicts of overwhelming intensity and/or fail to equip the child adequately to deal with conflicts within the normal range of early experience (Winnicott, 1965). Trauma (such as loss of a caregiver) or long-term abuse thus undermine personality development by intensifying incompatible wishes or reducing the child's capacity to resolve conflicts through mental work.

The child is predisposed to modify unacceptable unconscious wishes through a range of mental mechanisms aimed at reducing the sense of conflict. Defense mechanisms form a developmental hierarchy which reflects the degree of pathology experienced by the individual; developmentally early defenses, such as splitting, or projective identification, are normally associated with more severe disturbances. A neurotic symptom, such as phobic anxiety, may be understood as a result of displacement of fear from the representation of one model of interaction (e.g., father–child) to another (e.g., teacher–child). Considerably more resistant to therapy is the more primitive defense of splitting of affect, whereby a child alternately derogates and idealizes the caregiving figure. Immature or early defenses are assumed to reflect the absence of higher level, integrative capacities (Pine, 1985).

Psychodynamic therapists assume that the child's communication in the session has meaning beyond that intended by the child and, by analogous mechanisms, that the child's symptoms carry multiple meanings and reflect the nature of internal representations of others and their relationship to the child as the child perceives it. The therapist is able to bring the child's attention to aspects of his behavior which are ego-dystonic and hard to understand, and by making appropriate links illustrates to the child that they may be seen as rational in terms of unconscious mental experience and psychic causation (Sandler et al., 1980).

The relationship to the therapist has primacy, in that it provides a window on the child's expectations of others and can come to be a vehicle for the unwanted and disowned aspects of the child's thoughts and feelings. Transference displacement may include such aspects of past relationships or past fantasies about these as well as conflictual aspects of current relationships to parents, siblings, or important others. The child's verbal and nonverbal behavior (reenactments) have an impact on the clinician, and through exploring the role he or she has been placed in by the child, the therapist is able to achieve a better understanding of the child's representation of role relationships and feelings about them (Tyson & Tyson, 1986).

Modern psychodynamic child psychotherapy emphasizes the current state of the child in relation to his environment, history of past relationships, and adaptations to these. Psychotherapists generally recognize that the therapy they offer has an important holding or containing function in the child's life which, beyond interpretation and consequent insight, creates the possibility of a reintegration or reorganization of the child's internal world that in turn facilitates the child's adaptive development. The child therapist takes a "whole person" perspective, encompassing all aspects of the child's unfolding concerns (biological, environmental, intrapsychic). The establishment of a relationship with an adult which is as far as possible open and nonexploitative may serve as the basis of new internalizations, bringing about a healthier resolution of pathogenic experiences.

5.10.2 CONTEMPORARY TECHNIQUE OF PSYCHODYNAMIC PSYCHOTHERAPY WITH CHILDREN

5.10.2.1 Indications

There has been general agreement on the ideal indications for child psychotherapy (Dowling & Naegele, 1995). These have traditionally included: (i) good intelligence and capacity to verbalize; (ii) a relatively supportive environment; (iii) diagnostic assessment indicating the primacy of internal conflict underlying symptomatology; (iv) the absence of gross interferences between parents and child (indicating adequate internal–external object relations); (v) the presence of anxiety; and (vi) the absence of pervasive developmental disorder, psychosis, major deficiencies in psychological capacities, or family constellations likely to interfere with treatment (chaotic environments and uncooperative parents). Although there have always been a number of child psychotherapists who have attempted to work with psychotic and autistic children (e.g., Alvarez, 1993; Klein, 1936), the majority have felt that they cannot help these children using psychoanalytically oriented work.

Child therapists have also addressed other disorders, often called borderline (Rosenfeld & Sprince, 1963). This group has been described on the basis of records at the Anna Freud Centre (Fonagy & Target, 1996a, 1996b). Others have taken a more traditional, descriptive approach and arrived at very similar characterizations (Cohen, Towbin, Mayes, & Volkmar, 1994; Towbin, Dykens, Pearson, & Cohen, 1993). These children appear to suffer from a variety of deficiencies of psychological capacities, shown by, for instance, lack of control over affect, lack of stable self- and other-representations, and diffusion of the sense of identity. As we shall see, such children require substantial modifications of traditional technique (Fonagy & Moran, 1991). Whereas the less severe, so-called neurotic, cases are well-served by a therapeutic process aimed at addressing distortions in their mental representations of others or of their relationships to them, we have suggested that the more severely disturbed group of patients require developmental therapy which can strengthen and support their adaptive defenses, and assist them in labeling and verbalizing their thoughts and feelings (Fonagy & Target, 1996a). This distinction is most readily conceptualized psychologically in terms of the classical distinction between mental representations and the mental processes which generate them. Whereas so-called classical technique has its main effect on the organization and "shape" of the child's mental representations (Sandler & Rosenblatt, 1962), developmental therapy aims to help develop mental processes which have been inhibited during early development (Fonagy, Moran, Edgcumbe, Kennedy, & Target, 1993).

5.10.2.2 Forms of Intervention for Neurotic Children

Psychodynamic child psychotherapy involves the elaboration and correction of distorted, and often unconscious mental representations. The therapist, on the bases of the child's verbalization, nonverbal play, and other behaviors, attempts to construct a model of the child's conscious and unconscious thoughts and feelings and, using this model, helps the child obtain insight into why they may seem irrational and inappropriate. Such understanding may result in the integration of developmentally earlier modes of thinking into a more mature, age-appropriate framework.

This treatment involves the use of toys, games, and other devices to engage children in a process of self-exploration with an adult who is friendly but tries, within a trusting relationship, to draw attention to the unconscious determinants of the child's behavior. The therapist uses the child's fantasy, games, and associations in conjunction with other sources of data from the family, school etc., to construct a hypothetical picture of the child's unconscious mental life and current emotional concerns. In this way the therapist aims to help the child to understand his emotional responses, confusions, concerns about his body, the unconscious meaning of his presenting symptoms for the child, anxieties about unconscious aggressive or sexual impulses, and worries about his relationships with caregivers, siblings, and peers.

The techniques used by psychodynamic child therapists have been systematized, on the basis of empirical observation, by P. Kernberg (1995). In her studies, she was able to reliably distinguish a number of interventions on the part of the therapist, in addition to interpretive work, which may facilitate change in the patient's mental representations. In particular, she has delineated supportive interventions aimed at allaying the child's anxiety, and increasing a sense of competence and mastery through information, suggestions, reassurance, and empathy. In addition, she has observed facilitative statements which enhance and maintain therapeutic exchange with the child, when the therapist reviews, summarizes, or paraphrases the child's communication to that point. Related to this are clarifications aiming to either prepare the child for an interpretation, or direct his attention to noticeable aspects of his behavior. Although these are important distinctions, they are not placed within a theoretical context, and the therapeutic impact of the process is still seen as chiefly related to interpretations.

Analysts consider a number of aspects of a child's material when they try to interpret it. These include: (i) the main things the child talks about, especially what they say about themself, others, and the analyst, and the nature of the relationship these suggest between themself and objects in their mind; (ii) what is left out, such as not referring to arguments between the parents, to school, or to other important events in the child's life of which the analyst is aware; (iii) their nonverbal behavior, such as infantile gestures, unusual levels of activity, or avoiding entering the consulting room; (iv) their play, including roles assigned to the child, analyst, or play figures; (v) signs of the child's emotional state; and (vi) dreams that the child tells the analyst about.

The analyst is informed by, but does not necessarily mention, the child's past history and the contents of the previous sessions. While the analyst may often be able to make important connections between the child's analytic material and their past experiences, interpretations early on are generally restricted to the current conflicts which the child seems to be experiencing, in the immediate context through which the child brings these into the analysis. However, ultimately the analyst will aim to help the child develop an emotionally meaningful understanding of the connections between past experience and current conflict.

Kernberg (1995) distinguishes between three aspects of interpretations: interpretations of defenses show children how the therapist thinks they protect themselves from unacceptable thoughts, feelings, and actions. For instance, the therapist might suggest to the child "You often say that you are no good at things, perhaps because you are worried that people will think that you are big headed." Drawing the child's attention to these serves a dual function in that what is defended against is brought into awareness and, by implication, the child is also prompted to consider alternative strategies for coping with or expressing the ideas, impulses, or feelings previously warded off.

A second class of interpretation may address the child's wishes, which the therapist thinks may underlie his behavior. Most frequently, these two classes of interpretation are offered together, with the therapist leading the patient to see the unconscious wish by showing the child how he protects himself from it. The therapist might say "I think you secretly wish to feel much better than everyone else, and that is why you are frightened of seeming to be big-headed."

Some child therapists address the child's past experience as part of a causal account of the child's current state of mind. These reconstructions may be helpful, although few psychodynamic child therapists would nowadays feel that the actual past experience needs to be uncovered in order for the child's problems to be adequately addressed. More commonly, interpretations may make reference to current experience, particularly in relation to the therapist. The latter, so-called transference interpretations aim to identify the role in which the therapist experiences being placed by the child. The analyst further assumes that this role corresponds to an internal representation of a relationship in the child's mind. Thus, for example, a child who places the therapist in the role of a critic is assumed to be externalizing an internal representation of a figure who constantly undermines the self, and bombards it with disparagement and criticism. "I think you are so worried about me criticizing you because there is a terrible voice inside your head which says that you are such a naughty child that nobody could love you." It is important to note that analysts do not assume that such a figure actually exists in the child's life; an "internal object" may be a separated off part of the child's self-representation, which has been felt to be too destructive and aggressive for the child to be able to like himself. Interpretation eventually addresses this facet as well, by showing the child how unacceptable he finds the small amount of residual envy or destructiveness which has remained part of the self-structure, and through this gradually modifies the child's internal standards, allowing it to experience his destructiveness as less catastrophic.

Whether the content of the interpretation concerns defenses, wishes, or past or current experience, the underlying structure of child analytic interpretations is largely similar. The analyst focuses on the child's anxiety in relation to the above domains, in particular the emotional states they generate. Thus, destructive impulses are most likely to be taken up in terms of the anxiety the child feels about his angry feelings. A further important focus is explicit recognition that the child is actively struggling against certain wishes, and that aspects of current and past experience have necessitated the use of defenses. In psychoanalytic shorthand, this is referred to as "interpreting the conflict." Thus, rather than saying "You seem to be feeling very angry with me today," an analyst might say "You seem anxious, maybe because you feel angry." Naturally, this could be an inappropriate interpretation if the child was consciously aware of feeling angry, and not in conflict about this. However, in this case too, the analyst attempts to find the source of any current anxiety, for example, that the anger might destroy the otherwise valued relationship with the analyst.

The middle phase of analysis focuses particularly on the systematic use of transference interpretations to begin the "working through" process.

Transference is facilitated by: (i) the therapist's implicit offer of help and relatedness coupled with a basic stance of acceptance, encouragement to express thoughts and feelings, attention to resistances, and attunement to the child's predicaments; and (ii) a therapeutic structure that emphasizes regularity, consistency, and the specialness of the sessions (Chethik, 1989). Every action of the therapist conveys to the child that this time and space is set aside to better understand what bothers the child.

Signs of readiness for termination of the therapy are found both within and outside the sessions. Of course, sustained symptomatic improvement is important. Improvements in family and peer relationships are noted. The child's ability to make use of parents, teachers, and other people as sources of help and advice, and as models for identification, suggests that the analysis is becoming less necessary. Perhaps the most important indication for termination is evidence that the child is able to take advantage of normal developmental opportunities, to cope more effectively with stress and conflict, and to respond with greater freedom and mastery to demands for adaptation, coming from inside and outside.

Kernberg (1995) proposed the following specific features as showing readiness to end the therapy: (i) the child's statements about the therapist during the session convey an internalization of the analytic function, for example, comments about their sense of having been listened to or helped to make connections; (ii) the therapist finds more opportunities for interpretation, as opposed to clarifications or confrontations; (iii) the child introduces more material from current reality, suggesting a healthy decrease of investment in the analysis; (iv) there is more reflectiveness and capacity to use interpretations and resolve conflicts; (v) greater freedom, expressiveness, and pleasure in play; (vi) increased modulation of feelings, which permits discussion of experiences of sadness, concern, and gratitude; (vii) evidence of new adaptive interests; (viii) insight, humor, and a healthy capacity in the child to laugh at himself; (ix) flexible and adaptive coping and defensive operations, permitting the child to assume responsibility for their own actions; and (x) predominance of age-appropriate behavior, posture, and appearance.

5.10.2.3 Treatment Technique with Non-neurotic Disorders

More recently, the psychodynamic approach has been extended to apply not only to so-called neurotic disorders, but also to the understanding and treatment of borderline, narcissistic, delinquent, and conduct disordered youngsters (Bleiberg, 1987, 1994a, 1994b; Marohn, 1991; O'Brien, 1992; Rinsley, 1989), as well as schizoid and even psychotic children (e.g., Cantor & Kestenbaum, 1986). Clinical work with these more severely disturbed children quickly highlights the limitations of the "classical" analytic strategy. For example, the child's anxiety may not be accessible to awareness, and referring to it simply leaves the child confused. Also, there may be little evidence that the child is "struggling" against wishes, even when these are clearly socially unacceptable. In other children, defenses, as normally conceived, may be hard to identify. All these cases remind us of the need to reconsider child psychoanalytic techniques.

Bleiberg, Fonagy, and Target (1997) identify two clusters of youngsters who may be regarded as suitable for modified psychodynamic therapy, notwithstanding the severity of their disorder. They suggest that these clusters have in common the presence of at least one emotional disorder, for example, depression, dysthymia, generalized anxiety disorder (GAD), separation anxiety disorder, and social phobia; however, these symptoms must be seen in the context of a broader disturbance of social and emotional development, including marked impairment of peer relationships, affect regulation, frustration tolerance, and poor self-esteem.

One subgroup, designated cluster A, are characterized by fragile reality contact and thought organization, idiosyncratic magical thinking, ideas of reference, suspiciousness, and deep discomfort in social situations. They can neither make full sense of the social world, nor communicate adequately their internal states. They resemble the cluster A *DSM-IV* personality disorder diagnoses for adults and children described by Cohen et al. (1994), and Towbin et al. (1993) as multiplex personality disorder. By contrast, cluster B children show (if referred below school age) a hunger for social response, intense often dramatic affect, clinginess, hyperactivity, and temper tantrums. School-age children may meet axis 1 criteria for attention deficit hyperactivity disorder (ADHD), conduct disorder, or mood disorder, but their lack of adequate affect regulation is the major feature of the picture: a sense of elation and blissful merger with others close to the child seems to alternate with rage and self-hatred. They have been linked to adult "dramatic" personality disorders (cluster B), and have been described by Bleiberg (1994a, 1994b) and by Petti and Vela (1990). We have linked both clusters to an impairment of reflective function (Bleiberg et al., 1997; Fonagy & Target, 1996a). As psychodynamic therapists have extended the scope of their work to include these groups of patients, their therapeutic approaches have increasingly emphasized aspects of interaction between child and therapist which promote opportunities for playing with ideas. To some degree, this is a shift of emphasis within existing therapeutic techniques, at the same time as including some new techniques which have previously been systematically excluded from psychodynamic work with neurotic children, because of the expected interference with therapeutic neutrality. All these strategies have in common an emphasis on the therapeutic value of play, not just in the sense of pretending, but of creating a safe opportunity for playing with alternative meanings of the child's experiences.

The main forms of intervention include: (i) enhancing reflective processes by encouraging the observation and verbalization of what it is the child is feeling, focusing on somatic and psychological experiences in the immediate situation; (ii) enhancing impulse control, by looking for ways of channeling impulses into socially acceptable forms of behavior, and increasing control over expression of feeling in action; (iii) enhancing cognitive self-regulation, both through strategies involving symbolization or metaphor, and through demonstrating the therapist's own capacities for reflection and moderation of experience through thinking and talking, rather than physical action or coercion; (iv) encouraging awareness of the feelings and thoughts of others, often initially focusing on the child's perceptions of the therapist's mental states, as a precursor to self-reflection; and (v) developing play, perhaps first with objects, then another person, ultimately with ideas, with the aim of showing the child that habitual thoughts and feelings are not the only way of seeing things, or necessarily the way that others see the world, and that not all adults relate to them as they may have been related to before.

Techniques with developmental disturbances does not involve working with the transference in the sense of expecting the child to "transfer" their thoughts and feelings about their parents onto the analyst. However, the child's feelings about the therapist remain central, because the clarification of the child's feelings about themself and about the therapist is sometimes the most effective route towards acquiring mentalizing capacity. This requires the therapist to convey that the child's affect can be understood and managed by another person, rather than compounding what might have been the child's original experience, of a parent who has to twist or cut off emotional contact with the child to make the closeness of an intensive relationship more bearable. Late in the therapy with a developmentally disturbed child, it may also become helpful to make interpretations of neurotic conflict, which would previously have been experienced as meaningless or invasive.

The approach described is based on the assumption that reflective or mentalizing function is a key, biologically prepared human capacity triggered by specific aspects of normal parenting. A number of children—which we group into two developmental and clinical clusters—suffer from combinations of constitutional vulnerability and environmental disadvantage that create significant deficits in their ability to grasp mental states and find symbolic meaning in human behavior. This crucial deficit, as we have described, generates a host of problems in subsequent development and adjustment, including difficulties in relationships, impulse control, self-esteem, and overall difficulty in taking advantage of life's opportunities for growth.

We propose for these children a systematic psychodynamic psychotherapeutic approach aimed at enhancing the capacity to mentalize. While achieving such a goal is a by-product of traditional child psychoanalytic technique—and "psychological mindedness" is considered a precondition for child analysis proper—we suggest that a well-defined and deliberate focus on enhancing mentalization can lead to more effective and more specifically tailored approaches for a broad range of children with serious disturbances.

A therapeutic focus on mentalization, of course, does not preclude a variety of other therapeutic approaches, such as pharmacotherapy, family therapy, and cognitive-behavioral treatment. In effect, we propose that a psychoanalytic approach which promotes mentalization provides a conceptual glue to hold together a variety of interventions in a coherent treatment plan of greater clinical effectiveness (Bleiberg, 1994a, 1994b; O'Brien, Pilowsky, & Lewis, 1992).

Recasting psychoanalytic child therapy, from a predominantly insight-oriented, conflict-solving modality to a developmentally-based, mentalization-enhancing approach, brings it closer to the mainstream of contemporary developmental research and other, more empirically supported therapies. In particular, commonalities—and differences—between the approach described here and cognitive therapy warrant brief discussion. Both cognitive therapy and this approach aim at effecting a change in the ways people organize and structure experiences. Cognitive therapy, however, is both more "active" and directive and more narrowly focused on specific maladaptive cognitive schemas, for example, the particular cognitions underlying low self-esteem. By contrast, enhancing mentalization—while more targeted and "active" than traditional child psychoanalyses—aims at promoting a broad set of capacities, or mental processes, rather than correcting specific cognitive distortions.

The most important differences between the two approaches arise from the psychoanalytic origins of the psychotherapeutic strategy described in this chapter.

(i) These approaches are based on the assumption that the child's symptoms, and the entire organization of their subjective world, primarily represents an unconscious adaptation to the child's perceptions of reality. Child analysts therefore anticipate that children will try to resist the therapist's efforts, and the possibility of change: both of these, though well intentioned, threaten the child's best effort at adaptation thus far.

(ii) Child analysts have been trained to look for, respect, and address the child's deepest anxieties, which are likely to include anxiety about exercising the particular capacity that the treatment aims to promote, the recognition of mental experiences, and habitually thinking in terms of these to give the social world meaning and predictability.

(iii) Psychoanalytic training, supervision, and personal treatment should have helped the therapist to use her own thoughts and feelings to understand and empathize with the child's inner world, without getting stuck in response to the child's "concrete" ways of relating to themself and others.

5.10.2.4 Working with the Parents

Regardless of the child's predominant disturbance, it is generally helpful for the therapist to have meetings with the parents or other caregivers, aiming to enhance their sensitivity to the child's worries, limitations, and needs. This may involve work on aspects of the child's environment or family which seem to impinge on the child's development, and the exploration of ways of freeing the child from avoidable stresses. Sometimes this involves offering parents therapy for themselves, but much more often it is enough to help the parent to think more objectively and productively about the child, and to find together ways of overcoming obstacles to the child's positive development. Interventions range from concrete suggestions and strategies to helping the parents to be more understanding of their child's thoughts and feelings. The analyst may show the parent distortions affecting the relationship, for instance, where the mother identifies her son with her husband, and then unconsciously expresses the anger she feels towards her husband to the child, generally an easier and more available target.

Discussion of the child's symptoms aims to help the parents to develop more awareness of the nature of the child's difficulties and feelings, and (often) insight into possible reasons for these to have arisen and become entrenched. Parents may tend to minimize the difficulties facing the child. For example, in one family the parents needed to be helped to recognize their child's distress when they compared the child's ability to make friends with that of his much brighter and more attractive brother; the parents had felt that this comparison would encourage the child to try harder, not understanding that the child's difficulty went far beyond what could be corrected by greater effort. This sort of discussion may be combined with thinking about better ways of managing practical problems, for instance, major tantrums in response to separation. The parents can also be shown connections between external events and stresses and symptoms, whether somatic, emotional, or behavioral. Some stresses (e.g., an inappropriate school setting) can be removed, while others (such as having a physically handicapped sibling) of course cannot, but even here ways of limiting pressure and damage may be found.

5.10.3 THE OUTCOME OF PSYCHODYNAMIC TREATMENT FOR CHILDREN AND ADOLESCENTS

Research in the field of child therapies has very much lagged behind the adult literature, in terms of both number of studies and quality of design (e.g., Barnett, Docherty, & Frommelt, 1991). This lag has been greater still in the area of psychodynamic therapies, partly because of a traditional antagonism among psychodynamic clinicians towards empirical evaluation, but also because of specific methodological difficulties in the design of studies of long-term, intensive treatments, where choosing a suitable control group poses practical and ethical problems, and the treatment goals are relatively difficult to operationalize (usually what is sought is a change in unconscious psychic structure shown through subtle but pervasive personality changes, as opposed to change in more specific symptoms). For these reasons, evaluations of nonbehavioral therapies for children have most often been conducted by behaviorally-oriented clinicians, as a comparison condition for a trial of behavior or cognitive-behavior therapy (Shirk & Russell, 1992); they have also generally been administered in the form of brief, group therapy (to maintain comparability with the other treatment being evaluated) rather than longer-term, individual sessions as would be used in clinical practice (Kazdin, Siegel, & Bass, 1990b; Silver & Silver, 1983).

5.10.3.1 Reviews and Meta-analyses of Studies of Efficacy

Possibly partly for the reasons given above, meta-analyses of child therapy outcome studies have found psychodynamic and interpersonal therapies to be less effective than behaviourally-oriented techniques (Casey & Berman, 1985; Weisz, Weiss, Alicke, & Klotz, 1987). Weisz et al. (1987), for example, found an effect size exactly twice as great for behavioral therapies (0.88 vs. 0.44, $p < 0.05$). A further factor contributing to the difference has been identified by the authors of these meta-analyses, who found in both cases that the difference was reduced to nonsignificance once outcome measures very close to techniques practiced in the behavior therapy sessions were excluded from the comparison. Nevertheless, it remains a challenging fact that across the three studies which included some variant of brief, psychodynamic therapy, the mean effect size was negligible (0.01). If this were due to the use of therapeutic procedures in research studies which would never be expected to be effective in clinical practice, as persuasively argued by Shirk and Russell (1992), then it is imperative that the superior effectiveness of the procedures which would be used clinically be demonstrated. Thus far, the evidence from reviews of routine clinical work is dispiriting for psychodynamic therapy, as it is for child therapies of all orientations (see below), but the very small number of studies of outcome for this sort of therapy in a research setting which *do* use normal clinical procedures give more reason to be optimistic (see Section 5.10.3.3).

5.10.3.2 Review of Effectiveness in the Clinic

Serious doubt has been cast on the generalizablility of the lab-based studies of all forms of child treatment included in meta-analyses.

Weisz and Weiss (1989) observed that the meta-analyses to date had involved studies which did not represent normal clinic populations or practices. In particular, subjects were recruited rather than referred, samples were chosen for specific problems (e.g., phobias) on which the therapy was focused, therapists were specially and recently trained in the techniques to be evaluated. It was therefore felt necessary to see whether the good outcomes reported in these studies were also seen in the clinic.

The strategy was to compare 93 referred children who had received at least five sessions of therapy with 60 dropouts from the same clinics who had been offered treatment but did not attend. There were no significant differences on demographic or clinical variables between these groups when referred. The findings were very negative. There were no differences in outcome between treated and untreated children; both improved to an extent equivalent to the improvement found in untreated controls in other studies.

This first study of clinic-based treatment has generated increasing interest in the problem of applying research findings to clinical practice (see, for example, Hoagwood, Hibbs, Brent, & Jensen, 1995; Kendall & Southam-Gerow, 1995; Weisz, Weiss, Morton, Granger, & Han, 1992). Weisz, Donenberg, Han, and Weiss (1995) have reviewed evidence relating to the gulf between efficacy (in lab studies) and effectiveness (in clinic settings) in an attempt to disentangle the reasons behind the difference. The clinic-based studies included in their survey were few (only nine could be found in a thorough search, three of them carried out before 1960) and methodologically very limited, and one important point made by the authors is that well-designed effectiveness studies are desperately needed. They then attempted to test eight plausible reasons for the much larger effect sizes found in lab-based outcome studies, by conducting comparisons between over 100 of these studies, according to the presence or absence of possible mediating factors. They found that two did appear to be relevant (greater severity of clinical problems in clinic samples and greater likelihood of behavioral approach in lab studies). This, then, clearly suggests that the structured approach of behaviorally-oriented treatment tends to lead to greater effectiveness, and while it is clear that better-quality studies of the nonbehavioral therapies are badly needed, it may also be appropriate for psychodynamic clinicians to be considering whether their therapies can be made more focused on explicit goals, although these are likely to be formulated in terms of unconscious, intrapsychic structure and mechanisms.

5.10.3.3 Individual Studies of Outcome of Psychodynamic or Interpersonal Therapies

There have been very few studies of intensive, long-term psychoanalytic psychotherapy for children and adolescents.

A chart review of the outcome of 763 cases in child psychoanalysis has been carried out at the Anna Freud Centre in London (Fonagy & Target, 1994, 1995b; Target & Fonagy, 1994a, 1994b). While this retrospective methodology has severe limitations, the study reached a number of robust conclusions which need to be explored further in controlled, prospective investigations. The main findings were as follows.

(i) Attrition was low compared to reports of other treatment approaches. Overall, 18% of patients withdrew from treatment within six months, and as this made it unlikely that an analytic process would have been established and resolved, these children were excluded from the following analyses (further studies of attrition were, however, carried out).

(ii) Children with pervasive developmental disorders (e.g., autism) or mental retardation did not do well, even with prolonged, intensive treatment. Children with serious disruptive disorders also had relatively poor outcomes.

(iii) Younger children improved significantly more during psychodynamic treatment, and gained additional benefit from four to five times weekly sessions.

(iv) Anxiety disorders, particularly specific rather than pervasive symptoms, were associated with a good prognosis, even if the primary diagnosis was of a different type (e.g., disruptive disorder).

(v) Among children with emotional disorders, severe or pervasive symptomatology responded very well to intensive treatment (four to five sessions per week), but did not show satisfactory rates of improvement in nonintensive psychotherapy.

(vi) Predictors of improvement varied considerably between subgroups of the full sample, and by subdividing the sample according to diagnostic group and developmental level, it was possible to predict a majority of the variance in outcome within the subgroups.

We will now turn to smaller-scale, but prospective studies of psychoanalytic psychotherapy with children, beginning with the earliest systematic studies in the 1960s. After that, we will look at evidence on the efficacy of some forms of intervention based on modifications of psychodynamic psychotherapy.

Heinicke (1965) reported a study of a group of children aged 7–10 with developmental reading disorders linked to emotional symptoms. These children received psychoanalytic psychotherapy, either one or four sessions per week for two years. Greater improvement was found in the group receiving more frequent therapy. Heinicke and Ramsey-Klee (1986) extended this study, hoping to maximize the impacts of different treatment frequencies. They added a third group, matched to the first two, who received therapy once a week for the first year and four times a week for the second. Outcome was measured in terms of the referral problem (reading level) and general academic performance, together with a standardized psychodynamic diagnostic profile. At termination of therapy, there were no significant differences between the three treatment conditions, but at one-year follow-up, the groups which had received either four times a week treatment throughout, or once a week followed by four times a week, showed continued improvements on all measures, greater than those of the once a week group. It therefore seemed that more intensive treatment in the second year of treatment had a beneficial effect.

This study attempted to do three important things: (i) to evaluate the effectiveness of intensive and nonintensive psychodynamic therapy for emotional and learning disturbances; (ii) to isolate the impact of treatment frequency, which is of interest in a variety of therapies, and particularly—for practical and theoretical reasons—in psychodynamic treatment; and (iii) to measure change in both objective, service relevant ways, and ways consistent with the theoretical perspective. In all these respects, the study was innovative. There were difficulties with it, reflecting the methods prevalent in all outcome research 30 years ago when the basic design was planned. Thus, diagnostic characteristics of the sample were poorly described, the projective tests and diagnostic interview were of unknown reliability, and the therapy was not described in full detail, just being stated to be analytically oriented. The study does, however, clearly raise the possibility that for certain children, perhaps those with comorbid emotional and developmental disorders, intensive psychotherapy may offer more profound benefits than the same type of treatment offered once a week.

Moran and Fonagy have carried out a series of studies which overcame the problems of diagnosis and outcome measurement by choosing a group of physically ill children where difficulty in treating the medical condition was thought to be due to severely self-destructive behavior, sabotaging the treatment. The group chosen suffered from so-called brittle diabetes, and the studies assessed the effectiveness of adding psychoanalytic treatment to the existing medical care.

The first study (Moran & Fonagy, 1987) explored the relationship between metabolic control and the content of psychoanalytic sessions, in a single case study of an adolescent girl. Process reports were rated for the presence of psychodynamic themes; the association of certain themes with subsequent improvement, demonstrated through independent measures of diabetic control, was shown using time-series analysis. The second study by these authors (Moran, Fonagy, Kurtz, Bolton, & Brook, 1991) compared two matched groups of 11 diabetic children with highly abnormal blood glucose profiles and histories of regular admissions to the hospital. All patients were offered inpatient treatment, for the treatment group 15 weeks of intensive (three to four sessions per week) psychoanalytic psychotherapy was added. The children in the treatment group showed considerable improvements in diabetic control, maintained at one year follow-up; those in the comparison group had returned to pretreatment levels of metabolic control within three months of discharge from the hospital.

The third study (Fonagy & Moran, 1990) involved of a series of experimental single case investigations. The effect of brief psychoanalytic treatment on growth rate (measured by changes in height and bone age) was examined in three children whose height had fallen below the fifth percentile for age. In each case, treatment was linked to accelerated growth and a substantial increase in predicted adult height.

A different, ongoing study should be mentioned, in spite of methodological drawbacks, because of its attempt to assess outcome in clinically meaningful ways, and for its attention to a particularly needy (and costly) group. Lush, Boston, and Grainger (1991) compared 35 children in psychotherapy who were fostered or adopted with 13 similar children for whom psychotherapy had been recommended but did not start. The children were aged 2–18 years, and they mostly received weekly sessions for at least one year. For ethical reasons, children could not be randomly allocated to treated and untreated groups; the study was naturalistic. A further drawback was that, because no measures suitable for the assessment of psychodynamic change existed, measures were developed specially for the study and used without prior evidence of reliability or validity. However, there are indications that the therapy did benefit these deprived children. Preliminary results have been reported on the first 20 children to be treated. Sixteen cases made "good progress," as judged by therapists ratings and generally confirmed by parents' and external clinicians' opinions. An informal comparison was made with seven similar (but not matched) control children; none of these had improved during the same period.

Smyrnios and Kirkby (1993) have reported a comparison between 12 sessions of focal psychodynamic psychotherapy, and open-ended, nonfocused psychodynamic treatment with children aged 5–9 years. The mean number of child sessions was 10 for the time-limited condition and 27 for the unlimited condition. The parents of children in each treatment group were seen by a different therapist for guidance intended to support the child's treatment within a psychodynamic/family systems orientation. As with the individual therapy for the children, this parent work was much more focused on the identified problems and goals in the brief therapy condition. A further, minimal contact control condition involved assessment and feedback sessions only, with encouragement to the families to work at the goals by themselves. The groups were small, beginning with 10 children per condition, which had fallen to between six and eight by the time of the four year follow-up. The authors report that although pre- to post-treatment gains were significant for each condition, by follow-up, children in the time-unlimited condition no longer showed a significant improvement over the pretreatment levels of symptomatology as rated by the parents. Goals were found to be equally well attained at post-treatment and at follow-up in each of the conditions. Teachers' ratings of social adjustment did not show significant improvement for children in any condition, either at post-treatment or follow-up (there were trends towards improvement for all conditions, and the insignificant results may well reflect the small numbers involved). Essentially, children in the minimal contact control group showed improvements almost as great as those in the two treatment groups, and on one measure the time-limited treatment group did better than the open-ended one. The authors conclude that it may be most cost-effective to offer assessment and feedback rather than treatment to children such as those in this study.

There are several points that need to be made in interpreting the results of this study, some acknowledged by the authors.

The time-limited and minimal contact groups were both treated or assessed by one therapist, while the time-unlimited group were treated by a different therapist. This may well mean that therapist skill or commitment was not equal in the different conditions.

Although the assessments at pre- and post-treatment were carried out by an independent clinician, assessments at the four year follow-up were carried out by one of the authors who had also been the therapist for the time-limited and minimal treatment conditions. This would be likely to introduce a bias in favor of finding greater improvement in those conditions, not only because of therapist expectations, but also because parents interviewed by their child's therapist might be more likely to be positive than those seen by a stranger. Follow-up assessments by the children's teachers did not confirm the differences between groups found by the clinician interviewer.

It is mentioned that families in the minimal contact condition were in fact offered regular therapy sessions (presumably for child and parents separately, as for the other families) after a 12-week wait, although we are not told how many took this up. Thus, although the authors make an attractive argument that assessment only may be the most useful form of intervention, it seems unsafe to regard this group as untreated. In addition, it is stated that the majority of families across conditions sought further treatment during the follow-up period, which obscures the pattern of findings at follow-up.

The small sample size (down to an average of seven per group at follow-up) is unfortunate in that it casts doubt on generalizability and may have prevented certain trends from reaching statistical significance.

Despite these cautions, the study is a useful attempt to examine highly important questions, of whether evaluation alone may be as helpful as treatment, and whether offering more treatment produces better outcome. Although the authors intended to investigate the importance of the number of treatment sessions, it may be that the goal-oriented approach of both the time-limited and the minimal contact groups was helpful, and was the major difference between these groups and the open-ended one. It may also be, as the authors suggest, that the minimal contact condition inadvertently mobilized a useful sense of agency in the children and parents by helping them to clarify their goals and then encouraging the family to work towards them themselves. The open-ended treatment group therefore not only had a different therapist from the other two, but also had a far less focused and enabling approach.

5.10.3.4 Evaluation of Modifications of Psychodynamic Therapy

We will now more briefly survey some studies which have included forms of therapy related to psychodynamic therapies, or which have found some evidence of efficacy when it has been included as a control condition. Again, we will start with the earlier studies.

The pioneering study of Kolvin et al. (1981) will be included for what it can tell us about the amenability of different groups of children to treatment, with its careful design and relatively large sample size, even though it concerned therapy delivered through the school, and therefore difficult to apply directly in clinical psychology practice.

The study compared four forms of school intervention for nearly 600 children, found to be showing either neurotic or disruptive behavioral problems. These children were selected by screening 4300 children. The aim was to assess ways of helping maladjusted children within school, without recourse to psychiatric referral. The children were dichotomized in two major ways: younger vs. older (either 7–8 or 11–12 years old), emotional vs. disruptive disorders. These disorders were not defined by psychiatric diagnosis, but by extreme scores on measures of psychological adjustment in school, personality functioning, and peer acceptance. Children were randomly assigned to one of the four treatment conditions: (i) parent counseling—teacher consultation (three terms): social workers offered casework to parents and consultation to teacher; (ii) psychodynamic group therapy (one term only): the younger group played and were encouraged to reflect on feelings, while the older children discussed emotional issues; (iii) (a) behavior modification, for the older children only (two terms): attempted to alter behavior through systematic reinforcement, working towards specified individual goals; (b) nurture work, for younger children only (five terms): enrichment of social experience in small group with leader selected for warmth and motherliness, some shaping of desirable behavior; (iv) no treatment control condition. There were between 60 and 90 children in each age × treatment group.

Outcome was assessed at 18 months after the beginning of treatment, and at three years. In line with other intervention studies, children with emotional disorders were found to have significantly better outcome on the whole than those with disruptive behavior, irrespective of age and treatment type. It was also found that girls had significantly better outcome across groups. Generally, psychodynamic group therapy had the best outcome, and behavior modification was also helpful for the older children. Both were significantly more effective than counseling parents and teachers, or no treatment. Interestingly and unexpectedly, these differences between treatment and control groups widened over time, so that the effect of intervention appeared to be increasingly evident, even two years after it had ended. As Kolvin et al. (1981) note, the most effective interventions were in fact the briefest, and therefore easily the most cost-effective.

Psychodynamic group therapy was carried out over just one term, but the effects were very clear two and a half years later. This was a surprising finding, and it is not clear to what extent it might have been specific to the school setting; the intervention might not have had the same impact in a different context. School is a very important and familiar social context for children, one which may be able to facilitate and sustain considerable therapeutic impact. Similarly encouraging results have been reported in other smaller scale, more recent studies (e.g., Lochman, Coie, Underwood, & Terry, 1993). It is also unfortunate that the length of treatment was not consistent across the conditions; it is just conceivable that the briefer treatments were more effective because they were briefer, certainly this is a factor which needs to be considered more seriously in research on the impact of psychotherapies for children, as Smyrnios and Kirkby (1993) have indicated.

Another study in which psychodynamic therapy has been used as a comparison treatment has been reported by Szapocznik et al. (1989), who treated disruptive adolescent boys from Hispanic families, using either structural family therapy or individual psychodynamic therapy, compared with a recreational control group. All groups were seen for 12–24 sessions over up to six months. On parent-rated measures of child behavior, child psychodynamic functioning and family functioning, both family therapy and individual psychodynamic treatment led to significant gains, and these gains were not significantly different from each other. However, at one-year follow-up, although child behavior was still improved in both treatment groups, family functioning had deteriorated in the individual therapy group, continued to improve in the family therapy group, and stayed the same in the control group. If this finding proved to be generalizable beyond Hispanic families with conduct-disordered adolescent boys, then it would point to a very important problem in using individual psychodynamic therapy with children or adolescents, that although the child might get better, even sustaining the improvement a year later, the family might function less well over time.

Another study, which like the Kolvin report found a supportive psychotherapy group to be unexpectedly beneficial, was carried out by Fine, Forth, Gilbert, and Haley (1991). They were interested in evaluating the efficacy of social skills training in the treatment of major depression or dysthymia. The patients were 47 adolescents who had been referred for psychiatric treatment, and were assigned to a 12-week therapy group using either supportive therapy or social skills training. Forty-one percent of the patients were receiving concurrent treatment, either psychotherapy, medication, or both. Against expectations, adolescents in the therapeutic support group were significantly less likely than those given social skills training to be diagnosed as depressed following treatment ($p < 0.03$), and had significantly lower scores on the Child Depression Inventory (CDI) self-report measure of depression ($p < 0.05$). These group differences were no longer significant at follow-up, but this appeared to be a result of diminishing sample size rather than a change in relative rates of depression.

As the authors point out, in the absence of an untreated control group, it is not possible to be confident that the two treatments improved on the spontaneous remission rate; 68% of adolescents in the study were no longer diagnosable at nine months follow-up, and in Kovacs, Gatsonis, Paulauskas, and Richards (1989) study the median time to recovery was 9.5 months. This suggests some beneficial impact of therapy, but it is difficult to be sure how comparable the samples in the different studies were. The high proportion of adolescents receiving other treatments in the study by Fine and co-workers also raises a major problem of interpretation. Nevertheless, the authors acknowledge the unexpected superiority of the therapeutic support group over the "active" treatment, and provide an interesting discussion of this. There were indications from process measures that adolescents in the social skills training group were considerably less engaged and more avoidant. The authors suggest that social skills training may be too demanding for clinically depressed adolescents, but that they may become able to use this approach as they become less depressed. They suggest that a fruitful approach might be to offer therapeutic support which introduces social skills training at a later stage.

This is reminiscent of some other studies where a behaviorally-oriented treatment has apparently been perceived by children in clinical samples as less acceptable. For instance, Apter Bernhaut, and Tyano (1984) reported that hospitalized adolescent patients with obsessive compulsive disorder (OCD) refused to cooperate with behavioral treatment, but did accept and improve with supportive psychotherapy. Given that most outcome studies with children and adolescents have used nonreferred, convenience samples, this introduces a note of caution into the common conclusion that cognitive-behavioral treatment is more effective; if it were less likely to be accepted by children with a clinical level of disorder, then there would probably be a higher rate of attrition, and a lower overall improvement rate than the outcome research would suggest. This probably underlines the need for the development of cognitive behavior therapy (CBT) manuals appropriate to referred children rather than to the milder and/or less complex cases recruited for many outcome studies. Some such manuals have been written and successfully tested for clinical samples (Kendall, 1994; March, Mulle, & Herbel, 1994).

An important development in the area of relatively brief, manualized but nonbehavioral therapies for children and adolescents is Interpersonal Psychotherapy for Adolescents (IPT-A: Moreau, Mufson, Weissman, & Klerman, 1991). This is an adaptation of a treatment approach developed for depressed adult patients (IPT: Klerman, Weissman, Ronsaville-Chevron, & Chevrones, 1984), which focuses on a specified range of interpersonal problems which may underlie the individual's affective state. Although those who have developed this treatment approach distinguish it clearly from psychodynamic therapy, in its focus on interpersonal as opposed to intrapsychic difficulties, and its model of depression as rooted primarily in disrupted attachments rather than aggression (see Mufson, Moreau, Weissman, & Klerman, 1993), the contrast they make applies more to classical than to contemporary psychoanalytic thinking, and we include IPT-A here as an approach closely related to certain strong trends in psychodynamic work.

IPT for adults has been tested in several clinical trials, notably the National Institute of Mental Health collaborative study of the treatment of depression (Elkin et al., 1989). This adult therapy was tested for a group of 38 adolescent in-patients diagnosed as suffering from major depression in an open trial (Robbins, Alessi, & Colfer, 1989). Robbins and co-workers reported that 47% of patients showed clinically significant improvement with IPT alone. (Lack of response was associated with dexamethasone nonsuppression and "melancholic subtype.") The nonresponders were then treated with a combination of tricyclic antidepressant and this version of IPT; 92% then responded. Unfortunately, since there appears to have been a 50% placebo response rate (see Mufson et al., 1993), the 47% improvement is not impressive, the approach obviously needs further evaluation, and there is a strong case for introducing modifications to the adult manual, as have the developers of IPT-A (Moreau et al., 1991). The authors of the adapted treatment approach have conducted an open trial using this modified, manualized approach with 14 adolescents (Mufson et al., 1993). By week 3 of the 12 week trial, two of the 14 patients had dropped out and one had been excluded for noncompliance. Of the remaining 11, 9 showed a significant decrease in depressive symptomatology, and 10 no longer met criteria for major depression. One could therefore regard this as a 71% success rate, which is encouraging. A randomized controlled trial is now in progress.

5.10.4 LIMITATIONS OF PSYCHODYNAMIC APPROACHES

A series of limitations render psychodynamic approaches vulnerable to being seen as impractical, unscientific, and uneconomical.

(i) Little operationalization in most descriptions of the treatment, whose value is attested to largely by selected material from individual cases.

(ii) Little attention to what forms of technique may be appropriate for children with a particular diagnosis or psychodynamic formulation.

(a) Very limited evidence of efficacy, especially support from randomized controlled trials.

(b) A prolonged treatment, with rather vague or global goals, raising considerable doubts about cost-effectiveness.

Psychodynamic child psychotherapists are therefore facing great challenges to their convictions and, as managed care restricts payment for such lengthy and poorly supported treatments, to their professional survival. Nevertheless, we hope to have indicated in this chapter that these real and legitimate challenges are now being fully recognized and actively addressed by psychoanalytically-oriented child therapists.

5.11.1 INTRODUCTION

Psychopharmacology as a treatment modality for children and adolescents is a relatively young discipline that is based more on the collective experiences of clinicians than on empirical verification of the effects of various classes of psychoactive medications on childhood disorders. This is one of the reasons why, until the mid-1990s, pharmacological therapy was seen as the treatment of last resort. Indeed, it was rarely considered during initial treatment formulation until all other treatment modalities, such as psychoanalytic and psychosocial interventions, had been exhausted. Child and adolescent psychiatrists followed two simple guidelines when considering the use of medication. First, because the rationale for using psychotropic medication for specific disorders was not well established in children, they were concerned that they may actually do more harm than good in prescribing medication before trying other therapies. Thus, they were adhering to one of the fundamental principles of medicine: *prima non nocere* ("first do no harm"). Of course, in some cases, appropriate use of medication may have been withheld for several weeks or months while alternative, but eventually ineffective, therapies were used. Second, they followed another principle of medicine: when in doubt, don't. In so doing, they may have actually not prescribed medication to some children who would have benefited from it. Even as late as in the 1970s, few child and adolescent psychiatrists prescribed medication for childhood disorders (Towbin, 1995) and, when they did, it was typically for an early variant of what is now called attention-deficit hyperactivity disorder (ADHD).

Few would argue that the situation is vastly different today. Although there is still a paucity of empirically based studies on the use of psychotropic drugs in the treatment of childhood disorders, medication is considered, along with other treatment modalities, an integral part of a treatment plan (Kaplan, Simms, & Busner, 1994; Olfson, Pincus, & Sabshin, 1994). Given our current understanding that medication alone is rarely sufficient in the treatment of a childhood disorder, pharmacotherapy is now considered an important, and often necessary, part of a multimodal treatment plan. Modern child and adolescent psychiatrists who espouse the biopsychosocial model of childhood disorders understand that psychopharmacology, like any other single modality treatment, is limited in scope because it focuses on only one aspect of the child. Given that children develop in an interactional biological, social, and cultural matrix, effective interventions must be multimodal, multifocused, and multidisciplinary in nature (Singh, Parmelee, Sood, & Katz, 1993; Werry, 1993).

Undoubtedly, psychopharmacology is a major component in the treatment of childhood disorders and, as more research is conducted on its use, it is likely to solidify its role as the cornerstone of a comprehensive treatment for childhood disorders. Approximately 12–22% of American children (i.e., up to 14 million children) have a diagnosable mental illness, and it is very likely that many of these children may benefit from psychopharmacologic treatment (Institute of Medicine, 1990). This means that unless all professionals who treat childhood disorders have a working knowledge of psychopharmacology, they will not be able to make informed judgements about a necessary and important component of treatment for many children.

Although we often assume that psychiatric treatment and the prescription of psychotropic medication is solely in the domain of psychiatrists, the fact is that the majority of prescriptions for psychotropic medication written for psychiatric disorders are by family practice and primary care physicians who have limited training in mental health (Beardsley, Gardocki, Larsen, & Hidalgo, 1988). Psychologists assume a major role in the baseline assessment of the child and his family and contribute to the case formulation. In addition, they are often responsible for monitoring the child's response to medication (Ellis, Singh, & Singh, 1997). Because they are the primary therapist for the child's psychosocial treatment, psychologists are in an ideal position to monitor symptomatic improvement, observe the emergence of side effects, and check for medication compliance. Having a good knowledge of psychopharmacology enables the psychologist to play an active collaborative role in recommending medication and dosage changes to the child's physician.

In this chapter, we begin with a brief historical introduction to child psychopharmacology, followed by sections on the prevalence of psychopharmacology of childhood disorders, general principles of pharmacotherapy, factors that affect the outcome of psychopharmacologic treatment, assessment and clinical formulation, and psychopharmacologic treatment of childhood disorders. Finally, we present our view of future directions for research and practice. We use the term psychotropic drug in this chapter to refer to any pharmacological agent that is prescribed for the explicit purpose of bringing about behavioral, cognitive, or emotional changes in the child. The term psychoactive drug is used in a more general sense to refer to any pharmacological agent that may have these effects regardless of the physician's intent when prescribing this type of medication. We use the term child to include children and adolescents, and he or his in a generic sense to include reference to boys and girls.

5.11.2 HISTORY OF PEDIATRIC PSYCHOPHARMACOLOGY

Pediatric psychopharmacology began with Bradley's (1937) serendipitous finding that benzedrine affected the behavior disorders of children. However, little progress was made in the general field of psychopharmacology until the biological revolution in adult psychiatry began in the early 1950s. While conducting animal experiments, the Australian psychiatrist Cade (1949) noted that lithium carbonate made the animals lethargic, prompting him to use the drug with agitated psychiatric patients for its sedative effects. This led to the search for other drugs that could be used with adult psychiatric patients. The explosive growth of psychotherapeutic drugs in the 1950s changed the nature of American psychiatry and psychopharmacology became the mainstay of psychiatric treatment, especially for patients with severe mental illness.

The findings in adult psychopharmacology were extrapolated for use in child and adolescent psychiatry. From the 1950s, and especially during the 1960s, case reports and experimental studies began to appear that reported the effects of antipsychotic, antidepressant, "minor tranquilizer," and stimulant medications for a number of childhood psychiatric disorders. While these case reports and studies had serious methodological flaws, often being devoid of any experimental controls, soft evidence accumulated on the effects of certain drugs for specific disorders. For example, stimulants were generally found to be effective with many children with hyperactivity, imipramine (an antidepressant) was found to be effective for treating enuresis, and several antipsychotic medications were found to be effective for psychosis and aggressive behaviors.

The 1970s heralded an increasing interest in the scientific evaluation of existing drugs as well as in the development of related compounds in each drug class. Several advances were made in this period, including: (i) the development of diagnostic criteria for psychiatric disorders (e.g., research diagnostic criteria, *DSM*) so that the same disorders could be targeted across drug studies; (ii) increasingly sophisticated methodologies for drug evaluation studies; (iii) development of reliable and valid instruments sensitive to drug effects; (iv) increasing knowledge of pharmacokinetics of psychiatric drugs used with both children and adults; and (v) increasing monitoring of intended and adverse effects of drugs, both in the short- and long-term. Further, children were found to be drug responsive to a number of conditions that had previously not been the focus of pharmacotherapy, including eating disorders, aggressive conduct disorders, separation anxiety disorders (school phobia), bipolar disorders, depressive disorders, and Tourette's syndrome.

New drugs were added during this period of explosive growth in the use of pharmacotherapy. For example, anticonvulsant medications (e.g., carbamazepine, valproate) were found to be effective not only for seizure disorders but also for treating some children with bipolar disorder. The selective serotonin reuptake inhibitors (e.g., fluoxetine, sertraline, paroxetine) and the serotonergic-specific tricyclic drug, clomipramine, were found to be useful for a number of conditions, particularly depression and anxiety disorders, including obsessive-compulsive disorder. Further, dopamine receptor antagonists (e.g., clozapine, risperidone, olanzapine) that have far fewer neurological adverse effects than the traditional neuroleptics (e.g., chlorpromazine, thioridazine), and two new antidepressants (i.e., venlafaxine, nefazodone) were added to our pharmacotherapeutic armamentarium. Indeed, the search for new drugs that are more effective and have a better adverse effects profile than those currently available is one of the most vigorous and exciting areas of research in child psychiatry today.

Two other developments that occurred during this period should be noted. First, there was an increasing sophistication in the research methodology used to assess drug effects.

According to Werry (1993), because child psychiatry was preoccupied with psychoanalytic theory until the late 1970s, there was a lack of research in pediatric psychopharmacology. To a large extent, this void was filled by experimental and clinical psychologists who had better training than child psychiatrists in research methodology. They brought to the field of pediatric psychopharmacology experimental designs that could be used for clinical trials, and they were able to undertake complex statistical analyses of the data from experimental studies. Further, and in contrast to adult psychiatry, they emphasized the use of reliable and valid measures, including laboratory measures and rating scales, and the need for assessing the effects of medication on behavior, learning, and academic performance. However, one of the consequences of psychologists being more active than psychiatrists in psychopharmacological research was that they emphasized psychosocial rather than biological variables.

Second, beginning in the late 1980s, there was much negative media attention given to the use of Ritalin for the treatment of hyperactivity and attention deficit disorder (ADD: Brotman, 1992) and this negative attention is evident even in the late 1990s. One of the problems noted by the media was that this drug was prescribed excessively and probably inappropriately for many children. For example, Safer and Krager (1992) found that in Baltimore County, MD, the use of Ritalin increased fivefold from 1981 through 1987—far faster than one would have predicted from the figures on the prevalence of ADD in children. The media and litigation blitz which lasted about two years had a major effect on the prescribing practices of physicians in this particular county. Although the prescriptions for Ritalin decreased by 40% during this period, Safer and Krager reported that 36% of the children who discontinued Ritalin experienced major academic problems (i.e., failing grades, suspension from school) and another 47% had mild to moderate academic problems (e.g., lower grades, in-school detention). Further, as the number of prescriptions for Ritalin decreased during this period, there was concurrent fourfold increase in the number of prescriptions for tricyclic antidepressants among children with ADD. As the tricyclics have more troublesome side effects than Ritalin, the outcome for these children was not positive at all.

More recently, consumer groups and the Church of Scientology have attacked the use of fluoxetine (Prozac) on the basis of a report by Teicher, Glod, and Cole (1990) which reported the (re)emergence of severe suicidal preoccupation in six patients with severe depressive disorders following treatment with Prozac. However, none of the six patients actually attempted suicide while being treated with this drug. Further, studies have shown that Prozac is no more likely to induce suicidal feelings than any other antidepressant (Fava & Rosenbaum, 1991) and, at least in one study, it was found that the incidence of suicidal ideations was greater in patients treated with imipramine (a tricyclic antidepressant) or placebo than with Prozac (Beasley & Dornseif, 1991). Because research shows that the risk of Prozac-induced suicide is extremely low and that the suicide rate in untreated major depression is as high as 15%, the Federal Drug Administration (FDA) did not support the contentions of consumer groups or the Church of Scientology and refused to withdraw Prozac from the market (Burton, 1991). Although this controversy is related to adults, fluoxetine is also used with adolescents in the treatment of major depressive disorders, obsessive-compulsive disorder, and anxiety disorders (Popper, 1995). The effects of such controversies will affect the use of this drug with adolescents in the future.

Finally, the contribution of psychopharmacological research in developmental disabilities to the general field of child and adolescent psychopharmacology needs to be mentioned. From the mid-1960s until the 1980s, most child psychiatrists had an overwhelming interest in hyperactivity and ADHD and focused their research on the effects of stimulants on this disorder. Their interest in other disorders and other classes of drugs was minimal during this period. However, spurred by the methodological review of Sprague and Werry (1971), psychologists began testing the effectiveness of neuroleptics and other classes of drugs that were the mainstay of psychopharmacological treatment in developmental disabilities, especially for treating aggressive, self-injurious, and stereotypic behaviors (Aman & Singh, 1988; Singh, Ellis, & Singh, 1994; Singh, Guernsey, & Ellis, 1992; Singh & Winton, 1989). Much of the research on the psychopharmacology of the developmental disabilities since the mid-1970s has been methodologically innovative and experimentally rigorous. What we have learned from this endeavor has contributed much to the development of high-quality research in the psychopharmacology of child and adolescent disorders generally.

Since the 1980s, there has been an exponential growth in the number of studies published on the effects of medication in childhood disorders. The field of psychopharmacology of childhood disorders is rapidly achieving respectability and scientific credibility, and the launching of a specialist journal in 1990 (*Journal of Child and*

Adolescent Psychopharmacology) is an indication of the coming of age of this field.

5.11.3 PREVALENCE OF PSYCHOPHARMACOLOGY

Prevalence studies of pharmacotherapy for childhood disorders tell us something about the nature and patterns of drug usage in the treatment of psychiatric disorders in this population. Prevalence figures can also be useful in determining whether medication is being overused for certain disorders, or whether given drugs or classes of drugs are being overused for given symptoms or disorders. For example, the continuing debate about the excessive use of Ritalin is based in part on the number of prescriptions written each year for children with ADHD (Safer & Krager, 1992). Further, prevalence data also provide a useful guide to the way specific drugs are prescribed, evaluated, and monitored in clinical practice (Kaplan et al., 1994). As we have observed in the field of developmental disabilities (Ellis et al., 1997), prevalence studies are useful for examining the nature of the variables that are associated with drug use. These include, but are not limited to, characteristics of the child, physicians prescribing the medication (e.g., child psychiatrists, primary care physicians), the cultural and social milieu of the child, and psychosocial variables associated with drug use. Thus, prevalence studies provide us with a global picture of the patterns of psychopharmacological treatment for childhood disorders in general, and specific disorders in particular.

5.11.3.1 Developmental Disabilities

The best prevalence studies of pharmacotherapy have been published in the field of developmental disabilities (see Singh, Ellis, & Wechsler, in press). Following the seminal work of Lipman (1970) on the use of psychotropic drugs in residential facilities, a large number of prevalence studies have investigated the use of psychoactive medication in residential and community facilities for individuals with developmental disabilities. Overall, institutional surveys show that psychotropic drug usage ranges from a low of 19% to a high of 86%, with the majority of studies reporting prevalence rates between 30% and 50%. The use of seizure medication in institutions ranges from a low of 24% to a high of 56%, although typically it is between 25% and 45%. Together, psychotropic and antiepileptic medication usage in institutions ranges from 50% to 70%, with some individuals being prescribed both types of drugs concurrently.

Overall, there are fewer community surveys and these show that psychotropic drug usage with children ranges from 2% to 7%, and for adults it ranges from 14% to 36%. The use of seizure medication in community settings ranges from 12% to 31% for children and from 18% to 24% for adults. The combined prevalence of psychotropic and antiepileptic medications ranges from 19% to 33% for children and from 36% to 48% for adults.

Singh et al. (in press) have noted that various factors influence psychotropic drug use in individuals with developmental disabilities. For example, increasing dosages have been found to correlate highly with increasing age and decreasing intellectual impairment. There is a strong relationship between the type of residential facility and the use of medication to control behavior problems, with more medication being used in larger facilities and in facilities with very restrictive environments. Further, there is a strong positive correlation between the number and severity of an individual's behavior and psychiatric problems and the use of medication (Aman & Singh, 1988). For example, those who exhibit aggression, hyperactivity, self-injury, screaming, or anxiety are more likely to receive drug treatment than those who exhibit milder and less disruptive problems, such as noncompliance.

5.11.3.2 Attention-deficit Hyperactivity Disorder

Since the late 1960s, there has been increasing interest in the use of psychotropic drugs, especially psychostimulants, in the treatment of attention-deficit hyperactivity disorder (ADHD). Most of the early estimates came from the media rather than from scientific prevalence studies. For example, it was reported in the media that between 5% and 10% of students in Omaha public schools in 1970 were receiving stimulant medication for hyperactivity (Maynard, 1970), although later it was found that these figures actually were for children with learning disabilities. In any case, media estimates of the use of stimulants have continued to be published because of the concern that stimulant medication is prescribed for children who may not actually have ADHD and is being used in lieu of effective academic instruction (e.g., Gates, 1987; Hancock, 1996; Johnson, 1988; Landry, 1996).

In one of the earliest prevalence studies, Stephen, Sprague, and Werry (1973) estimated that 2–4% of school children in the Chicago area were receiving medication for hyperactivity in the 1970–1971 school year. Gadow's (1981) review of the use of drug treatment for hyperactivity suggested that the prevalence rate was between 1% and 2%, with considerable variability across geographic regions. Safer and Krager's (1988) longitudinal community surveys in Baltimore County, MD, showed that the prevalence of drug prescriptions doubled every 4–7 years, with about 6% of children in public elementary schools in this county receiving medication for hyperactivity by 1987. Further, almost all the prescriptions (99%) were for stimulants (93% methylphenidate, 4% pemoline, and 3% dextroamphetamine), and the ratio of boys to girls receiving the medication was 5:1. Sherman and Hertzig (1991) reviewed the state prescription records in 1986 and found that 0.4% of all 3–17 year olds in Suffolk County (Long Island, NY) received at least one prescription for methylphenidate for hyperactivity. The medication was typically prescribed by local pediatricians, and the ratio of boys to girls receiving methylphenidate was 6:1.

5.11.3.3 Serious Emotional Disturbance

Children with serious emotional disturbance (SED) typically have comorbid psychiatric disorders for which psychotropic medication is often indicated. They are prescribed more psychotropic medication than their peers without SED, regardless of whether the mental health services are provided in a psychiatric hospital (Singh, Landrum, Donatelli, Hampton, & Ellis, 1994) or in the community (Landrum, Singh, Nemil, Ellis, & Best, 1995). Further, the prevalence of psychotropic medication used with children with SED receiving inpatient psychiatric services or community-based services is much higher when compared to the 11% usage in school-identified students with SED (Cullinan, Epstein, & Sabornie, 1992; Cullinan, Gadow, & Epstein, 1987). For example, Silver et al. (1992) reported 43%, Epstein, Cullinan, Quinn, and Cumbald (1994) and Epstein, Cullinan, Quinn, and Cumbald (1995) reported 27% and 30%, respectively, and Barber, Rosenblatt, Harris, and Attkisson (1992) reported a prevalence of 34% for just antipsychotic medication. Singh et al. (1994) reported that 64% of the children with SED at a psychiatric hospital received at least one psychotropic medication.

5.11.3.4 Other Disorders

There is a paucity of prevalence data on the use of medication for children with other psychiatric disorders. The best data we have on individuals with autism comes from a large study by Aman, Van Bourgondien, Wolford, and Sarphare (1995). The mean age of their sample of 859 individuals with autism was about 16 years. Of this sample, about 34% were taking some psychotropic medication or vitamin for autism or associated behavioral/psychiatric problems. Although about 19% reported having epilepsy, only 13% were actually taking anticonvulsant drugs. In total, over 50% of the sample were on psychoactive medication. There are no recent studies on the prevalence of psychopharmacological studies of children with depression. In two studies using selected samples of children being treated for depression, Kovacs, Feinberg, Crouse-Novak, Paulauskas, and Finkelstein (1984) reported that of the 65 children in their study, only two were on antidepressants, and another was treated with an antianxiety agent. In the other study, Keller, Lavori, Beardslee, Wunder (1991) reported that only one of 38 adolescents diagnosed as having an episode of major depression was treated with medication, in this case an antianxiety agent. As for enuresis, Foxman, Valdez, and Brook (1986) reported that 2% of a sample of 1724 5–13 year olds received medication (typically imipramine) for bedwetting. Although no drug prevalence data on children with Tourette's syndrome are available, one study in which a majority of the individuals with Tourette's syndrome were under 20 years of age reported that 71% of 1034 individuals had taken medication for Tourette's syndrome at some time, and 43% were taking medication at the time of the survey (Stefl, Bornstein, & Hammond, 1988). There are no reliable estimates of the use of medication in other childhood disorders.

These data provide a general view of the use of psychotropic and antiepileptic medication in a number of childhood disorders. However, many of the prevalence studies were poorly controlled, using ill-defined variables, small and selected samples, and so on, thus limiting the usefulness of the data that were reported. It is likely that the current use of medication in all childhood disorders is actually increasing because we have better-controlled studies than in the past indicating the effectiveness of newer medications, such as the selective serotonin reuptake inhibitors (SSRIs), with a number of these disorders. Obviously, there is a need for better controlled studies that examine the prevalence and patterns of drug use in children with various childhood disorders.

5.11.4 GENERAL PRINCIPLES OF PHARMACOLOGY

Psychopharmacology is a rapidly evolving area in child and adolescent psychiatry and it is important for clinicians working with children with psychiatric disorders to remain current with the research literature in this field. While we do not think that it is critical for nonmedical clinicians to be experts in the pharmacology of psychiatric drugs, it may be helpful for them to have a working knowledge of basic concepts in the field so that their collaboration with physicians can be more meaningful. For example, it may help them to better understand the theoretical bases of the choices made by a psychiatrist in the selection of specific agents for treating single or multiple childhood disorders. We will briefly mention three areas that are important for clinical psychologists as well as other nonmedical clinicians to be familiar with. However, we emphasize that this is a very complex, technical, and specialized field that cannot be adequately covered here, and we suggest that interested readers begin with general overviews (e.g., Clein & Riddle, 1995; Paxton & Dragunow, 1993) before delving deeper into the field.

5.11.4.1 Pharmacokinetics

Pharmacokinetics describes the time course and effects of drugs and their metabolites on the body. Thus, it describes what the body does to a drug. The most important pharmacokinetic factors that affect the time course and the effects of drugs on patients include: (i) absorption, which is the process that determines how a drug travels from the site of administration to the site of measurement (e.g., plasma, whole blood); (ii) first-pass effect, which is the hepatic extraction of orally administered drugs before they reach the systemic circulation; (iii) distribution, which indicates how much of a drug is distributed to the various organs or sites of action throughout the body; (iv) steady-state concentration, which indicates the concentration of the drug when the amount administered is equal to the amount eliminated per unit time; (v) half-life, which is the time required for the concentration of the drug in plasma or whole blood to fall by one-half; (vi) elimination rate constant, which is the proportion of the drug in the body that is eliminated per unit time; (vii) clearance, which provides a measure of elimination of the drug from the body and is calculated by multiplying the amount of drug in the body by the elimination rate constant; (viii) first-order kinetics, which occurs when the amount of the drug eliminated per unit time is directly proportional to its plasma concentration; and (ix) zero-order kinetics, which occurs only when a fixed amount of the drug is eliminated per unit time regardless of plasma concentration. Data on these factors can be used to draw a unique kinetic profile of a given drug.

Together with pharmacodynamics, pharmacokinetics provides the bases for understanding the relationship of drug concentrations to clinical effects in children. Since the 1950s pharmacologists have developed the theoretical pharmacokinetic bases for most types of dosage regimens and have identified the therapeutic plasma concentration ranges for a number of psychotropic drugs that are currently used to derive rational dosage regimens (Evans, Schentag, & Jusko, 1986). Indeed, child psychiatrists rely on pharmacokinetic principles to optimize the effects of pharmacotherapy in children (Clein & Riddle, 1995; Greenblatt & Shader, 1987).

5.11.4.2 Pharmacodynamics

Pharmacodynamics deals with the relationship between drug dosage or concentration in the body and its drug effects, both desirable and undesirable. Thus, it deals with the mechanism(s) of drug action and generally describes what a drug does to the body. The most important pharmacodynamic considerations include: (i) receptor mechanism, which describes how the drug binds at the cellular level and initiates its pharmacodynamic effects; (ii) dose–response curve, which provides a plot of the drug concentration against the effects of the drug and allows comparison of the efficacy and potency of drugs; (iii) therapeutic index, which provides a relative measure of the toxicity and safety of a drug, and is calculated by dividing the median toxic dose by the median effective dose; (iv) lag time, which is the time taken for the full therapeutic effects of a given drug to appear, and the reasons for a delay in effects may be pharmacokinetic, pharmacodynamic, or both; and (v) tolerance, which refers to the responsiveness of a child to a particular drug as it is administered over time.

Children differ widely in terms of the drug dose that produces a given effect. Thus, clinicians must have a good knowledge of current pharmacodynamic principles to understand a child's response to psychotropic drugs (Dingemanse, Danhof, & Breimer, 1988; Paxton & Dragunow, 1993).

5.11.4.3 Pharmacogenetics

Pharmacogenetics deals with idiosyncratic or unusual drug responses that have a hereditary basis (Kalow, 1990). Responses to psychotropic and other drugs in children are modulated by their genetic predisposition. This is because "genes encoding enzymes or proteins that play a role in the drug response differ in some respect from one individual to the next" (Nebert & Weber, 1990, p. 469). When all other variables are held constant, the individual's pharmacogenetic response reflects a genetic difference in the metabolic rate when compared to that of a control subject. For example, Zhou, Koshakji, Silberstein, Wilkinson, and Wood (1989) compared the physiologic effects and the pharmacologic disposition of propranolol in a group of Caucasian Americans and a group of Chinese Orientals. They reported that the Chinese subjects were more responsive to the drug, displaying a larger reduction in the heart rate and blood pressure, because they metabolized the drug more efficiently than the subjects in the Caucasian group. According to Nebert and Weber (1990, p. 473), idiosyncratic drug responses that may be due to genetic variation in any of the subcellular steps involved in pharmacokinetics include the following mechanisms: (i) transport (absorption, plasma protein binding); (ii) transducer mechanism (receptors, enzyme induction, or inhibition); (iii) biotransformation; and (iv) excretory mechanisms (renal and biliary transport). Typically, clinical observations, family or twin studies, protein polymorphisms, animal modeling, and DNA polymorphism characterizations are methods used to discover new atypical drug responses that may have a pharmacogenetic basis. The clinical import of pharmacogenetics is that clinicians should be aware of the possibility of differences in drug response and dose requirements among children from various ethnic and racial groups.

5.11.5 FACTORS AFFECTING THE OUTCOME OF PHARMACOTHERAPY

The effects of psychotropic drugs are seldom determined solely by their pharmacological properties, such as those discussed above. Indeed, psychotropic medication is prescribed and used within a transactional system between the child, his family, physician and other clinicians, as well as others (e.g., teachers, peers) who are significant in the life of the child (Moerman, 1979; Singh & Aman, 1990). Of course, we must remember that children rarely, if ever, seek assistance from physicians directly; their parents and other caretakers do and, almost always, without asking for input from the child. The child's views of the treatment process, the child–physician therapeutic alliance, and the child's attributions of the effects of medication are also important and may be responsible for at least some of the effects of pharmacotherapy (Towbin, 1995). Further, other factors, such as compliance, placebo effects, and sociocultural and ecobehavioral factors, are important in treatment outcome. However, the majority of studies in child psychopharmacology have focused on biological variables (e.g., pharmacokinetics, pharmacodynamics, and pharmacogenetics) to the exclusion of virtually all others.

Singh and Aman (1990) noted that our knowledge of the intended effects of psychotropic medication in children is often based on an assessment of the changes in the target behavior, symptoms, and syndrome as a result of a controlled trial of a given drug. They criticized this approach on the grounds that it does not include the study of environment × behavior × drug interactions and inter-relationships. The majority of current psychopharmacological research in general focuses on the consequences of specific drugs or drug combinations on the target behavior or diagnosis, without regard to the setting events or contextual variables that may influence the effects of the medication. A transactional analysis would require that the effects of pharmacotherapy be explained in terms of the relevant contextual variables that transact to determine treatment outcome.

There are a large number of contextual variables that may contribute to the outcome of psychopharmacotherapy. While all variables cannot be covered here, we present diverse examples to show that assessment of treatment outcome is much more complex than has hitherto been noted in psychopharmacological research.

5.11.5.1 Behavioral Teratogenesis

Girls of child-bearing age are always cautioned about the potential interaction between pregnancy and nursing, the course of a psychiatric disorder, and psychotropic treatment (Coyle, Wayner, & Singer, 1976; Schou, 1990). With some drugs (e.g., lithium, valproic acid), there is a real possibility of a drug × pregnancy interaction which increases the risk of malformations in the unborn child and the potential for later developmental anomalies. For example lithium may increase the risk of fetal macrosomia, premature delivery, and perinatal mortality (Schou, 1990), and the teratogenic effects of valproic acid on exposed fetuses includes a 1–2% incidence of spina bifida (Centers for Disease Control, 1983)

5.11.5.2 Behavioral Toxicity

Behavioral toxicity refers to the undesirable effects of essentially therapeutic levels of medication clinically indicated for a given disorder (DiMascio, Soltys, & Shader, 1970). These undesirable effects may include anticholinergic effects, alpha-adrenergic blockade, and dopaminergic effects, among others. In behavioral terms, behavioral toxicity can be classified as a concurrent stimulus event that affects the ongoing interactions of the child. For example, take the case of a child who is on medication for a seizure disorder. The drowsiness produced by his anticonvulsant medication (e.g., phenobarbital) may cause him to function more poorly than he might in its absence. Thus, in this case, behavioral toxicity may operate concurrently with classroom instruction or activities at home. In assessing the effects of psychopharmacotherapy, clinicians should include measures of behavioral toxicity because it will assist the child's treatment team to arrive at risk-to-benefit treatment decisions on the basis of data.

5.11.5.3 Compliance

Compliance is the degree to which a child adheres to the recommended treatment plan of the treating physician. In children, compliance with medication is typically partial because they tend to take medication irregularly or less often than is prescribed. The reasons for medication noncompliance can be categorized as "rational, capricious, absolute refusal, confusion, or iatrogenic" (Janicak, Davis, Preskorn, & Ayd, 1993). Often, noncompliance occurs because of unpleasant side effects of the medication and the perceived stigma associated with taking medication in school. Some children believe that taking medication somehow lessens their control of their lives, or that the medication determines what they do. Medication compliance in children can be increased by: (i) having the child actively participate in treatment planning; (ii) explaining to the child before treatment begins the expected side effects of the medication; (iii) emphasizing the positive aspects of taking the medication as prescribed, and (iv) having the simplest drug regimen (e.g., taking medication once a day for long-acting drugs). Further, compliance can be increased by involving the family in the treatment process. Clearly, these psychosocial factors associated with medication compliance affect the outcome of psychopharmacologic treatment.

5.11.5.4 Comorbidity

Comorbidity, which is the presence of disorders other than the one targeted for treatment, affects treatment outcome because the additional disorders change the simple drug × disorder × environment interaction to a more complex drug × disorder_1 × environment × disorder_2 interaction, if there is just one comorbid disorder. This interaction may mean that a second treatment, which could be pharmacotherapy or an alternative, is necessary to control a comorbid disorder, resulting in drug_1 × disorder_1 × environment × drug_2 × disorder_2 interaction. Of course, other interactions may also occur, such as drug_1 × drug_2 interaction, and changes in the physiologically determined susceptibilities of the drugs to interact with the environment to produce certain unintended, positive or adverse effects (i.e., side effects). This scenario suggests that the child must be adequately assessed not only for the target symptoms, syndrome, or disorder but also for comorbid disorders. Further, the interactive effects of treatments × environments × disorders must be assessed during clinical treatment and under baseline, placebo, and treatment in research protocols. This is a critical consideration for many childhood disorders. For example, comorbid axis I psychiatric disorders are commonly associated with childhood depression and ADHD (Kye & Ryan, 1995). The clinical import of this variable is that comorbidity may contribute to differential response to psychopharmacologic treatment.

5.11.5.5 Placebo Effects

The placebo effect in pharmacology is the phenomenon that is observed when a child exhibits a clinically significant response to a physiologically inert substance. This is not a rare phenomenon as it may account for 30–70% of the therapeutic responses observed in psychopharmacologic treatment (White, Tursky, & Schwartz, 1995). The placebo response is not due to the psychopharmacological properties of the drug; that is, the outcome is not due to the effects of the prescribed intervention. It results from purely psychological effects as a consequence of expectancy of an outcome from the treatment. While a majority of the placebo effects are established simply by asking the child if he is feeling better or by having the child complete a rating scale that provides a measure of his subjective well-being, often placebo effects can also be measured objectively. For example, individuals given placebo treatment for anxiety disorder often show less autonomic nervous system arousal (e.g., decrease in heart rate, lower blood pressure). Although there is some evidence of sustained placebo response in adults, children relapse fairly rapidly, suggesting that continued monitoring of a placebo response is absolutely necessary in this population.

5.11.5.6 Reciprocal Interactions

In behavioral terms, reciprocal interactions are concurrent stimulus–response contexts that set the occasion for further interactions. This is an important variable that affects the course of psychopharmacotherapy because the initial effects of drugs on a child may also have an effect on the reactions of others who interact with him. This phenomenon was clearly illustrated in the stimulant treatment of children with ADHD in which (i) the drug increased a child's compliance with parent demands, and (ii) the parents, in turn, reduced their commands and disciplinary behaviors, while increasing their positive interactions with the child (Barkley & Cunningham, 1979; Cunningham & Barkley, 1978). This highlights the importance of assessing drug effects on reciprocal interactions of the child with significant others in his environment (e.g., parents, siblings, peers, teachers).

Although we have selectively discussed some factors that affect the outcome of psychopharmacologic treatment, there are many factors that should be monitored for their impact on the outcome of pharmacologic intervention.

5.11.6 ASSESSMENT AND CLINICAL FORMULATION

5.11.6.1 Comprehensive Assessment

A comprehensive psychiatric assessment is necessary before a child is given pharmacotherapy. The clinician's goal is to understand the child's presenting problems or symptoms within the context of the highest level of diagnostic sophistication that can be reached on the basis of a comprehensive multidisciplinary assessment. There are four levels of diagnostic sophistication: (i) symptomatic, which includes isolated symptoms (e.g., auditory hallucinations) that provide an indication of a possible diagnosis (e.g., psychosis, not otherwise specified); (ii) syndromic, which includes a constellation of signs and symptoms that have been present for a given time, and standardized inclusionary and exclusionary criteria can be used to derive a diagnosis (e.g., depression); (iii) pathophysiologic, which includes structural or biochemical changes (e.g., elevated thyroid function tests, lowered thyroid-stimulating hormone) that indicate the diagnosis (e.g., hyperthyroidism); and (iv) etiologic in which the diagnosis is based on known causative factors (Janicak et al., 1993). With children, most of the psychiatric diagnoses are at the syndromic level of sophistication because we do not currently have a good understanding of the etiologies of many childhood disorders. Thus, it is not uncommon to find wide variability in treatment outcome in children diagnosed with the same syndrome because they have similar presentations but with substantially different underlying mechanisms. This means that sometimes we treat children's behavioral symptoms or psychiatric disorders without fully appreciating their biological and genetic underpinnings or how these factors transact with the children's physical and cultural environment.

5.11.6.2 Baseline Assessments

A baseline assessment provides the basis for determining the child's psychopathological condition, indications for treatment, and the nature of the proposed treatment. It is multidimensional and multidisciplinary, incorporating assessments of the child's symptoms and functioning across multiple domains, as well as an evaluation of his family history and his physical and cultural environment. Typically, a baseline assessment includes: (i) source and the reason for referral, including the target symptoms that may be the focus of treatment; (ii) history of the presenting symptoms; (iii) psychiatric history and current mental status; (iv) developmental and medical history; (v) family and education/school history; and (vi) cultural context of the family (e.g., determine if there are any specific religious or cultural beliefs of the family that may interact with the child's psychiatric treatment in general, and psychopharmacological treatment in particular). Different mental health professionals may take the lead role in obtaining the baseline assessment data. Because of their broad-based training, child psychiatrists and clinical psychologists often assume a major role in these assessments, obtaining information on the child through structured interviews, behavioral observations, and standardized rating scales.

5.11.6.3 Disorder-specific Assessment Algorithms

Typically, clinicians develop a working hypothesis regarding the child's diagnosis during the initial assessments, or the child may be referred by another clinician for treatment of a specific disorder, such as ADHD. In such cases, clinicians may use an assessment algorithm designed to confirm the diagnosis and to provide data that can be used as the baseline for assessing treatment effects. For example, Table 1 presents the standard algorithm for screening children with ADHD at our clinic (see Garfinkel & Amrami, 1992). Assessment algorithms provide a distillation of current knowledge from multiple sources and disciplines regarding the assessment of a specific disorder. Further, they provide a useful framework for interdisciplinary assessments.

5.11.6.4 Baseline Assessments Specifically for Psychopharmacologic Treatment

The initial assessments can be used to determine the psychiatric diagnosis of the child, as well as to identify target symptoms best treated with pharmacotherapy (Sood & Singh, 1996). If a child is referred specifically for psychopharmacological treatment, he will need a baseline psychiatric assessment prior to initiation of medication. Premedication workup typically includes a complete medical history, and physical and neurological examinations. Further, if data from initial baseline assessments are unavailable, other data may have to be gathered prior to formulating a treatment plan.

A psychiatric interview with the child, alone and together with his parents, is undertaken to determine a psychiatric diagnosis or diagnoses for which medication may be indicated. Further, this assessment enables the clinician to identify the target symptoms for treatment. While it is often thought that medication is prescribed for a target disorder (e.g., bipolar disorder, ADHD), in reality this is not the case. The clinician targets specific symptoms that serve as markers for the underlying psychopathology and the changes in these symptoms over the course of treatment are used to evaluate the effects of medication. Multiple symptoms are used as markers because some may respond to medication before others. For example, if we take a child with bipolar disorder, his sleep and appetite disturbances will improve earlier than his mood. Further, the clinician is careful to determine the phase of the child's illness (i.e., acute, relapse, recurrence) because of its importance in clinical decision making with regard to initial treatment as well as the need for and duration of maintenance and prophylactic therapy. Information on the temporal patterns

Table 1 Screening algorithm for attention-deficit hyperactivity disorder.

Initial referral may be either from school or home
Begin teacher–parent–child observational rating scale (e.g., Conners)
Refer to pediatrician or child psychiatrist or both:
  Complete physical examination, including:
    screen for lead toxicity and iron-deficiency anemia
    screen for other nutritional deficiencies
    detailed neurologic assessment, including perceptual motor tests to rule out focal neurological deficit
    thyroid panel (if indicated)
  Complete history, including:
    antenatal and perinatal history
    developmental milestones
    sleep history
    social and family history
    school history utilizing school records, grade-level screening medical history, especially trauma, infection, neurologic history, and allergies
  Use cognitive testing to assess intelligence and learning disabilities and organic brain syndromes
    Wechsler Intelligence Scale for Children-III
    Woodcock–Johnson
    Other tests, as indicated
  Psychometric testing
    Gordon diagnostic system
    Continuous performance test
  Evaluation of home situation
    If the evaluation is consistent with ADHD, a trial of sympathomimetic medication may be initiated
    Evaluation to monitor side effects, effectiveness of medication, four times yearly; alternative pharmaceutical or other therapies may be considered

of drug response and the phase of a child's illness is critical in the overall pharmacologic management of the child (Janicak et al., 1993).

5.11.6.4.1 Physical examination

The standard physical examination includes recording the child's temperature, pulse rate, respiratory rate, blood pressure, height, and weight. Because drugs may have adverse effects on the developing fetus, girls of childbearing age should be given a pregnancy test.

5.11.6.4.2 Laboratory tests and diagnostic procedures

Many of these tests would have been done during the baseline medical evaluation and need not be repeated. According to Green (1995, p. 26), standard laboratory tests for a pre-medication work-up may include the following:

(i) Complete blood cell count (CBC), differential, and hematocrit.

(ii) Urinanalysis.

(iii) Blood urea nitrogen (BUN) level.

(iv) Serum electrolyte levels for sodium (Na^+), potassium (K^+), chloride (Cl^-), calcium (Ca^{2+}), and phosphate ($PO_4{}^{3-}$) and carbon dioxide content (CO_2).

(v) Liver function tests: aspartate aminotransferase (AST) or serum glutamic oxaloacetic transaminase (SGOT), alanine aminotransferase (ALT) or serum glutamic pyruvic transaminase (SGPT), alkaline phosphatase, lactic dehydrogenase (LDH), and bilirubin (total and direct).

(vi) Serum lead level determination in children under seven years of age and in older children, when indicated.

In addition, other laboratory tests may be indicated prior to using specific psychoactive medications. For example, thyroid function tests are recommended prior to using tricyclic antidepressants and lithium; kidney function tests prior to using lithium carbonate; baseline and periodic electrocardiogram (ECG) for tricyclic antidepressants and lithium; an electroencephalogram (EEG) for antipsychotics, tricyclic antidepressants, or lithium for those who "have a history of seizure disorder, who are on an antiepileptic drug for a seizure disorder, or who may be at risk for seizures" (Green, 1995, p. 27).

5.11.6.4.3 Behavioral observations and rating scales

Except in emergency situations (e.g., violent, explosive behavior), a child is observed for 7–10 days for patterns in his general behavior as well as the target symptoms before initiating pharmacotherapy. In addition to the psychiatrist, clinical psychologists are in the best position to provide valid and reliable observation data on the child's behavior from multiple settings. These observations are useful in determining the stability of the child's problems as well as the need for medication, should the child's condition improve substantially during the observation period.

Behavioral observations are labor-intensive and often impractical in clinical practice. Fortunately, there are various rating scales that can be used to obtain reliable data on a child across multiple settings and by multiple raters (Sood and Singh, 1996). For example, the child behavior checklist (Achenbach, 1991a) is used widely for initial assessment of children and adolescents referred for psychiatric assessment, and the various Conners rating scales are used extensively with children with ADHD (Conners, (1990). Interested readers should consult Aman (1993) and Sood and Singh (1996) who have reviewed an extensive array of rating scales that can be used for this purpose.

5.11.6.5 Clinical Formulation

The diagnostic formulation follows the standard biopsychosocial model, which means that biological, psychological, and social factors are taken into account in developing a comprehensive framework for understanding the child's symptomatic presentation. Once the relevant data are gathered, the clinician synthesizes the information and reaches a working diagnosis. However, before a psychiatric diagnosis is reached, any general medical condition that may account for the child's problems are ruled out. In addition, it is critical that deviation from the normal range of development is considered. Further, a child may have symptoms of multiple conditions and all relevant diagnoses need to be considered (e.g, ADHD and learning disorders).

In the diagnostic formulation for psychopharmacological interventions, the clinician pays particular attention to signs and symptoms associated with psychiatric disorders that have a biological basis. These disorders have the potential for being responsive to psychoactive agents. Much of this information is obtained from the clinician's use of a descriptive, phenomenological assessment of the child's feelings, emotions, and behaviors because it provides important insights into the child's disorder(s). Information on the clinical course helps the clinician to place the disorder in a specific context because many pharmacologically responsive disorders have "characteristic beginnings, occur during particular stages of development, or are associated with particular sequelae" (Walkup, 1995, p. 26). For example, attention and concentration difficulties at age 5 or 6 years may be related to ADHD but at age 15 or 16 years, these symptoms are more likely to be associated with a mood disorder (Walkup, 1995). Detailed family history is also useful in diagnostic formulation for a number of reasons, such as providing additional support for the clinician's working hypothesis. The clinician uses all of this information to formulate a treatment plan that includes pharmacotherapy as well as some type of educational and psychosocial intervention because pharmacotherapy alone is rarely sufficient for complete recovery.

5.11.7 PSYCHOTROPIC MEDICATION IN CHILDHOOD DISORDERS

The main psychopharmacologic agents used in children are presented in Table 2 by class, generic name, and trade name. What follows in each section is a discussion of a given class of medication, mechanism of action, indications, dosing, and adverse effects. Only general principles and procedures of psychopharmacologic therapies are covered because applications of this treatment modality to specific psychopathologies are discussed elsewhere. However, as a general rule, it must be remembered that psychopharmacologic treatment is typically used as one component of a broad therapeutic approach to help alleviate psychiatric symptoms in children. Medication provides symptomatic relief, allowing the child to function more fully at school and at home, and in his community. Further, medication usually relieves the child's symptoms of psychiatric illness but it does not remove vulnerability to its recurrence because the environmental and constitutional stressors that gave rise to the illness are not affected by the medication.

5.11.7.1 Antipsychotics

The antipsychotics have been called major tranquilizers because of an early observation that chlorpromazine, the prototypical drug in this class, produced somnolence and relaxation. This led to the mistaken belief that the major action of antipsychotics was sedative. Antipsychotics have also been called neuroleptics because they are noted for producing signs of neurological dysfunction, principally Parkinson's syndrome, and other extrapyramidal reactions. Typically, drugs that produce both antipsychotic and extrapyramidal effects are called neuroleptic drugs. While the term neuroleptic continues to be used interchangeably with antipsychotic, the discovery of clozapine, an antipsychotic that is not a neuroleptic, means that this practice may now be inappropriate.

The antipsychotics consist of a group of eight classes of drugs, including phenothiazines (e.g., chlorpromazine [Thorazin], fluphenazine [Prolixin], thioridazine [Mellaril]), thioxanthenes (e.g., thiothixene [Navane]), dibenzoxazepines (e.g., loxapine [Loxitane]), dihydroindoles (e.g., molindone [Moban]), butyrophenones (e.g., haloperidol [Haldol], droperidol [Inapsine]), diphenylbutylpiperidines (e.g., pimozide [Orap]), benzamides (e.g., sulpiride [Dogmatil]), and benzisoxazole (e.g., risperidone [Risperdal]). Pharmacologically, the major classes of antipsychotics are remarkably similar and, when given in equivalent doses, they produce comparable benefits and induce a similar range of adverse effects (see Table 3).

5.11.7.1.1 Mechanism of action

The antipsychotics produce their therapeutic effects by blocking the D_2 subtype of dopamine receptors, although some of them may block the D_1 receptors as well. Blockade of the dopamine receptors is also responsible for most of the neurological and endocrinological adverse effects of antipsychotics. The difference in the adverse effects profiles of the antipsychotics is due to the fact that some of the antipsychotics also block noradrenergic, cholinergic, and histaminergic receptors. For example, blocking of the alpha-noradrenergic receptors by some antipsychotics probably accounts for their hypotensive action. When compared to the low potency antipsychotics (e.g., chlorpromazine, thioridazine), those with high potency (e.g., haloperidol, pimozide) are typically less sedating, produce less hypotension, and they generally have less effect on seizure threshold, fewer anticholinergic effects, less cardiovascular toxicity, less weight gain, and minimal effect on bone marrow and liver. Risperidone, a new antipsychotic medication, has D_2 as well as serotonergic (5-HT2) antagonist properties and lacks the acute extrapyramidal adverse effects of the traditional antipsychotics. Clozapine, an atypical antipsychotic, has weak D_2 antagonist properties but a high affinity for D_4 dopamine receptors, as well as a relatively strong antagonistic interaction with central alpha$_1$-adrenergic, cholinergic, histaminic (H1), and serotonergic (5-HT2) receptors (Baldessarini & Frankenburg, 1991; Lieberman, Kane, & Johns, 1989). Like risperidone, clozapine also lacks acute extrapyramidal adverse effects.

Table 2 Psychoactive and psychotropic drugs by class.

Drug class/subclass	*Generic name*	*Trade name*
A. Antipsychotics		
Phenothiazines	chlorpromazine	Thorazine
	fluphenazine	Prolixin, Modecate
	mesoridazine	Serentil
	perphenazine	Trilafon
	thioridazine	Mellaril
	trifluoperazine	Stelazine
Thioxanthenes	chlorprothixene	Taractan
	thiothixene	Navane
Butyrophenones	haloperidol	Haldol
	pipamperon	Dipiperon
Rauwolfia alkaloids	reserpine	Rauloydin, Reserpoid, Sandril
Other antipsychotics	clozapine	Clozaril
	loxapine	Loxitane
	risperidone	Risperdal
	olanzapine	Zyprexa
B. Antidepressants		
Tricyclics	amitriptyline	Elavil, Amitril, Endep
	clomipramine	Anafranil
	desipramine	Norpramin, Pertofrane
	doxepin	Sinequan, Adapin
	imipramine	Tofranil
	nortriptyline	Pamelor
Monoamine oxidase inhibitors	isocarboxazid	Marplan
	phenelzine	Nardil
	tranylcypromine	Parnate
Selective serotonin reuptake inhibitors	fluoxetine	Prozac
	fluvoxamine	Luvox
	paroxetine	Paxil
	sertraline	Zoloft
Other antidepressants	bupropion	Wellbutrin
	trazodone	Desyrel
	venlafaxine	Effexor
C. Antimanics		
	lithium carbonate	Eskalith, Lithane, Lithobid
D. Anxiolytics		
Benzodiazepines	alprazolam	Xanax
	chlordiazepoxide	Librium
	diazepam	Valium
	lorazepam	Ativan
	oxazepam	Serax
	prazepam	Verstran
	temazepam	Restoril
	triazolam	Halcion
Antihistamines	diphenhydramine	Benadryl
	hydroxyzine	Atarax
	promethazine	Phenergan
Atypical anxiolytics	buspirone	BuSpar
E. Stimulants		
	amphetamine sulfate	Benzedrine
	dextroamphetamine	Dexedrine

Table 2 (continued)

Drug class/subclass	*Generic name*	*Trade name*
	methamphetamine	Desoxyn
	methylphenidate	Ritalin
	pemoline	Cylert
	mixed salts product[a]	Adderall
F. Antiepileptics		
	carbamazepine	Tegretol
	clonazepam	Klonopin
	diazepam	Valium
	ethosuximide	Zarontin
	felbamate	Felbatol
	gabapentin	Neurontin
	phenobarbital	Luminal, Gardenal
	phenytoin	Dilantin
	primidone	Mysoline
	sodium valproate	Depakene, Depakote, Epilim
	sulthiame	Ospolot
G. Others		
Beta-blockers	propranolol	Inderal
Alpha-2 blockers (nonspecific)	clonidine	Catapres
Alpha-2A blockers (selective)	guanfacine	Tenex
Opioid antagonists	naloxone	Narcan
	naltrexone	Trexan
Sympathomimetic amines	fenfluramine	Pondimin, Ponderax
Anticholinergics	benztropine	Cogentin
	biperiden	Akineton
	ethopropazine	Parsidol
	procyclidine	Kemadrin
	trihexyphendiyl	Artane

[a] Combination of dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine sulfate, and amphetamine aspartate.

5.11.7.1.2 Indications

In children, the antipsychotics are used mainly in the treatment of psychotic disorders, typically the positive symptoms, as well as other behavioral symptoms, such agitation, aggression, tics, and stereotypies (Green, 1995; Kutcher, 1997). The positive symptoms include hallucinations, delusions, thought disorder (i.e., incoherency), and catatonic symptoms (e.g., stupor, negativism, rigidity, excitement, and posturing) or bizzare affect. The negative symptoms, which include affective blunting, poverty of speech and thought, apathy, anhedonia, and poor social functioning, respond well to the atypical antipsychotics (e.g., clozapine, risperidone). Among the antipsychotics, haloperidol and pimozide are the drugs of choice for treating children with Tourette's disorder. The low-potency drugs (e.g., chlorpromazine, thioridazine) are used to treat mania and, as a last resort, to treat aggressive behavior and severe agitation in children. The high-potency drugs (e.g., fluphenazine, perphenazine) are used for severe insomnia and severe self-injury. Clozapine is useful in treating refractory psychosis in adolescence, and risperidone is useful in treating both positive and negative symptoms of psychosis, as well as some symptoms associated with pervasive developmental disorder. Until recently, antipsychotics have been used widely in the treatment of self-injury, aggression, and agitation in children with developmental disorders (Ellis et al., 1997).

In terms of effects, there is little data to support the use of one antipsychotic drug over another because the action of these drugs is related to their structural similarities (Janicak et al., 1993). Thus, clinicians typically base their choice of one antipsychotic over another with regard to the adverse effect profile of the drugs.

Table 3 Antipsychotic drugs, trade names, potencies, and potential adverse effects.

Antipsychotic drug	*Trade name(s)*[a]	*Potency*[b]	*Potential adverse effects profile*			
			Sedation	*Anticholinergic*	*Hypotension*	*Extrapyramidal*
Chlorpromazine	Thorazine, Largactil	100 (low)	strong	strong	strong	weak
Fluphenazine	Prolixin, Modecate	1.5–3 (high)	moderate	weak	weak	strong
Haloperidol	Haldol	2–5 (high)	weak	weak	weak	strong
Loxapine	Loxitane	10–15 (medium)	moderate	moderate	moderate	strong
Mesoridazine	Serentil	50 (low)	moderate	strong	moderate	moderate
Molindone	Moban	6–10 (medium)	moderate	moderate	weak	strong
Perphenazine	Trilafon	10 (medium)	weak	weak	weak	strong
Pimozide	Orap	1 (high)	weak	weak	weak	strong
Risperidone	Risperdal	2–3 (low)	weak	weak	weak–moderate	weak
Thioridazine	Mellaril	97 (low)	strong	strong	strong	weak
Thiothixene	Navane	2–5 (high)	weak	weak	weak	weak
Trifluoperazine	Stelazine	3–5 (high)	moderate	weak	weak	strong
Triflupromazine	Vesprin	25–50 (low)	strong	moderate	strong	moderate

[a] Not all drugs are approved for use in children or in all countries. [b] mg of drug equivalent to 100 mg chlorpromazine.

For example, because children should maintain a relatively high level of activity for their developmental and psychological well-being, the clinician may choose haloperidol (which has fewer sedative and cardiovascular effects) over chlorpromazine (which has fewer extrapyramidal complications). Further, our history of clinical experience suggests that some children do in fact respond to one antipsychotic but not to another. It may be that this is due to differences between the drugs in terms of absorption, distribution, accumulation at receptor sites, pharmacodynamic actions, metabolism of their derivatives, and adverse cognitive effects (e.g., as a result of sedation). In addition, the drugs may appear to act differentially if their effects are not compared at optimum dosages for the child.

5.11.7.1.3 Dosing and adverse effects

The recommended doses for antipsychotic drugs typically used with children are presented in Table 4. In general, oral dosage of the low-potency antipsychotics range between 3.0 and 6.0 mg/kg/day. On average, the dosage of high-potency antipsychotics range between 0.1 and 0.5 mg/kg/day, although dosages up to 1.0 mg/kg/day are not uncommon. The dosage of risperidone is about 1–3 mg/day or up to 85 μg/kg/day, the dosage for clozapine is between 3.0 and 5.0 mg/kg (Spencer, Wilens, & Biederman, 1995).

The side effects of the antipsychotics are presented in Table 5.

5.11.7.2 Antidepressants

As the name implies, antidepressants are used to treat depression in children and adults. The serendipitous finding that iproniazid, a drug used to treat tuberculosis, had mood-elevating properties and inhibited the enzyme monoamine oxidase led to the development of a class of antidepressants called the monoamine oxidase inhibitors (MAOIs). Some years later, the drug imipramine (Tofranil) was developed, followed by a number of others with a similar structure—the tricyclic antidepressants. A new generation of antidepressants have become available, with some of them (e.g., fluoxetine) enjoying remarkable clinical success in the treatment of depression.

5.11.7.2.1 Mechanisms of action

The different classes of antidepressants can be categorized according to their structure and/or presumed mechanism of action. For example, Janicak et al. (1993, p. 242) categorized them as follows:

(i) Heterocyclics (HCAs, e.g., imipramine, Tofranil), which block the neuronal reuptake of norepinephrine and/or serotonin.

(ii) Selective serotonin reuptake inhibitors (SSRIs, e.g., fluoxetine [Prozac]), which modify serotonin neurotransmission by inhibiting the reuptake carrier.

(iii) Monoamine oxidase inhibitors (MAOIs; e.g., isocarboxazid [Marplan]), which increase the concentration of several biogenic amines.

(iv) Aminoketones (e.g., bupropion [Wellbutrin]), whose most potent known effect is neuronal dopamine reuptake blockade, but whose mechanism of action is unknown.

(v) Triazolopyridines (e.g., trazodone [Desyrel]), which have mixed effects on the serotonin system, with the predominant effect being 5-HT2 receptor blockade.

(vi) 5-HT_{1A} receptor partial agonists (e.g., buspirone [BuSpar]), marketed as anxiolytics, but which also have proven antidepressant properties, especially with higher doses.

Although the different classes of antidepressants have specific mechanisms of action, in general, the antidepressants block the reuptake of one or more catecholamines (i.e., norepinephrine, serotonin, and dopamine), thereby decreasing or downregulating the number of postsynaptic receptors. The MAOIs have a different mechanism of action; they increase the availability of catecholamines by blocking the enzyme monoamine oxidase.

5.11.7.2.2 Indications

In general, the antidepressants are used with children to treat ADHD, obsessive–compulsive disorder (OCD), enuresis, depression, anxiety, and tic disorders. The tricyclic antidepressants (e.g., imipramine, desipramine, nortriptyline) are used to treat major depressive disorders (MDD), enuresis, ADHD, tic disorders, and anxiety disorders. Clomipramine has been found to be effective with OCD. The SSRIs (e.g., fluoxetine, sertraline, paroxetine, fluvoxamine) are used to treat MDD, OCD, and anxiety disorders. Bupropion is used to treat ADHD and MDD; trazodone for MDD, aggression, and insomnia; and venlafaxine for MDD, OCD, and anxiety disorders. The MAOIs are now rarely used with children because of potential problems with medication compliance and adverse effects in this population (Viesselman, Yaylayan, Weller, & Weller, 1993).

Table 4 Recommended doses for the various classes of psychotropic drugs.

Drug	*Average daily dose* *Children*	*Adolescents*
A. Antipsychotics		
Chlorpromazine (> 6 months of age)[a]	30–200 mg (2.5–6 mg/kg/day)	40–400 mg (3–6 mg/kg/day)
Thioridazine (> 2 years of age)[a]	75–200 mg (0.5–3 mg/kg/day)	10–200 + mg
Trifluoperazine (> 6 years of age)[a]	1–15 mg	1–20 mg
Thiothixene (> 12 years of age)[a]	2–10 mg	5–30 mg
Haloperidol (> 3 years of age)[a]	0.5–4 mg (0.05–0.15 mg/kg/day)	2–16 mg
Reserpine	0.02–0.25 mg	0.1–1.0 mg
Clozapine (> 16 years of age)[a]		50–200 mg (3–5 mg/kg/day)
Loxapine (> 16 years of age)[a]	5–50 mg	20–100 mg
B. Antidepressants		
Amitriptyline (> 12 years of age)[a]	30–100 mg (1–5 mg/kg/day)	50–100 mg (1–5 mg/kg/day)
Bupropion (> 18 years of age)[a]	25–150 mg	75–300 mg (3–6 mg/kg/day)
Clomipramine (> 10 years of age)[a]	25–100 mg	50–150 mg (2–3 mg/kg/day)
Desipramine (> 12 years of age)[a]	10–150 mg (1–5 mg/kg/day)	50–150 mg (1–5 mg/kg/day)
Fluoxetine (> 18 years of age)[a]	5–20 mg	10–60 mg (0.5–1 mg/kg/day)
Fluvoxamine (> 8 years of age)[a]	25–200 mg	50–300 mg
Imipramine (> 6 years of age)[a]	10–150 mg (1–5 mg/kg/day)	50–200 mg (1–5 mg/kg/day)
Notriptyline (> 12 years of age)[a]	10–100 mg	50–100 mg (1–3 mg/kg/day)
Phenelzine (> 16 years of age)[a]		15–45 mg (0.5–1 mg/kg/day)
Sertraline (not in children)[a]	25–100 mg	50–200 mg (1.5–3 mg/kg/day)
C. Antimanics		
Lithium carbonate[b] (> 12 years of age)[a]	300–900 mg	900–1200 mg (10–30 mg/kg/day)
D. Anxiolytics		
Alprazolam (> 18 years of age)[a]	0.25–2 mg	0.75–5 mg (0.02–0.06 mg/kg/day)
Chlordiazepoxide (> 6 years of age)[a]	10–30 mg	20–60 mg
Diazepam (> 6 months of age)[a]	1–10 mg	2–20 mg (max 0.8 mg/kg/day)
Lorazepam (> 12 years of age)[a]	0.25–3 mg	0.05–6 mg (0.04–0.09 mg/kg/day)
Diphenhydramine	25–200 mg	50–300 mg (1–5 mg/kg/day)
Hydroxyzine	25–100 mg	40–150 mg (2 mg/kg/day)
Buspirone (> 18 years of age)[a]	2.5–15 mg	5–30 mg (0.2–0.6 mg/kg/day)

Table 4 (continued)

Drug	*Average daily dose* *Children*	*Adolescents*
E. Stimulants		
Dextroamphetamine (>3 years of age)[a]	2.5–15 mg (0.15–0.5 mg/kg/dose)	5–40 mg (0.15–0.5 mg/kg/dose)
Methylphenidate (>6 years of age)[a]	2.5–30 mg (0.3–1 mg/kg/dose)	10–60 mg (0.3–1 mg/kg/dose)
Pemoline (>6 years of age)[a]	18.75–75 mg (1–3 mg/kg/day)	37.5–112.5 mg (1–3 mg/kg/day)
Mixed salts[c] (>3 years of age)[a]	2.5–30 mg	5–40 mg
F. Antiepileptics		
Carbamazepine[b] (>6 years of age)[a]	200–800 mg (5–20 mg/kg/day)	400–1000 mg (10–30 mg/kg/day; max dose 1000 mg/day)
Ethosuximide[b]	250–800 mg (20–30 mg/kg/day)	500–1500 mg (20–40 mg/kg/day)
Phenobarbital[b]	<250 mg (4–8 mg/kg/day)	75–250 mg (1–3 mg/kg/day)
Phenytoin[b]	<300 mg (7.5–9 mg/kg/day)	300–500 mg (6–7 mg/kg/day)
Primidone[b]	150–750 mg	750–1500 mg
Sodium valproate[b]	250–1000 mg	500–2000 mg
G. Others		
Propranolol	5–80 mg	20–140 mg (max 2 mg/kg/day)
Clonidine (not in children)[a]	0.25–0.3 mg (3–6 μg/kg/day)	0.3–0.4 mg (3–6 μg/kg/day)
Naltrexone (>18 years of age)[a]	10–50 mg (0.5–1.5 mg/kg/day)	40–120 mg (1–2 mg/kg/day)
Fenfluramine (>12 years of age)[a]	30–60 mg	40–100 mg (1–2 mg/kg/day)
Benztropine (>3 years of age)[a]	0.5–4 mg	0.5–6 mg (43–86 μg/kg/day)

[a] Recommended US Food and Drug Administration guidelines. [b] Dosage titrated by serum levels. [c] Combination of dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine sulfate, and amphetamine aspartate.

5.11.7.2.3 Dosing and adverse effects

The recommended doses for antidepressant drugs typically used with children are presented in Table 4. The dose of antidepressant drugs for children has to be individualized because of interchild variability in metabolism and elimination. In general, the typical dose for tricyclic antidepressants in children ranges from 2.0 to 5.0 mg/kg, with 1.0–3.0 mg/kg for nortriptyline. The potential cardiotoxic effects of the tricyclic antidepressants, and particularly the reports of sudden death associated with desipramine therapy (Riddle et al., 1991), have reduced the use of tricyclic antidepressants by some clinicians. The suggested daily dose for fluoxetine is 0.5–1.0 mg/kg; for paroxetine 0.25–0.70 mg/kg, for sertraline 1.5–3.0 mg/kg; and for bupropion 4.0–6.0 mg/kg/day in divided doses.

The side effects of the antidepressants are presented in Table 5.

5.11.7.3 Antimanics

Lithium carbonate is the main antimanic drug used to treat children who have bipolar disorder, with the anticonvulsants, carbamazepine (Ballenger & Post, 1980), and valproic acid (McElroy, Keck, & Pope, 1987) being used as alternative antimanic agents.

5.11.7.3.1 Mechanism of action

Little research has been done on the use of these antimanic agents with children, and their therapeutic mechanism(s) is virtually unknown.

Table 5 Psychiatric and behavioral indications and side effects of various classes of drugs.

A. Antipsychotics	
Indications:	Psychotic states, schizophrenia (exacerbations and maintenance); mania (in conjunction with lithium); behavior disorders with severe agitation, aggressivity, and self-injury; and dyskinetic movement disorders (e.g., Tourette's disorder and juvenile Huntington's disease)
Side effects:	Anticholinergic effects, including dry mouth, constipation, blurred vision, and urinary retention (most common with low-potency phenothiazines); extrapyramidal reactions, including acute dystonia, akathisia, and tremor (particularly with high-potency phenothiazines); neuroleptic malignant syndrome; tardive dyskinesia (lower risk with clozapine and risperidone); other central nervous system effects, including sedation, fatigue, cognitive blunting, psychotic symptoms, confusion, and excitement; orthostatic hypotension and cardiac conduction abnormalities; endocrine disturbances (e.g., menstrual irregularities and weight gain); gastrointestinal distress; skin photosensitivity; granulocytopenia and agranulocytosis (clozapine); and allergic reactions.
B. Antidepressants	
Indications:	Enuresis; attention-deficit/hyperactivity disorder; major depressive disorder; and anxiety disorders (including school phobia, separation anxiety disorder, panic disorder, and obsessive-compulsive disorder)
Side effects:	*Tricyclics:* Anticholinergic effects, including dry mouth, constipation, blurred vision, and urinary retention; cardiac conduction slowing (treatment requires EKG monitoring), mild increases and/or irregularity in pulse rate, and mild decreases or increases in blood pressure; confusion or the induction of psychosis; seizures; rash; and endocrine abnormalities *Monoamine oxidase inhibitors:* Mild decreases or increases in blood pressure; drowsiness; weight gain; insomnia; and hypertensive crisis with nonadherance to dietary restrictions (necessary to eliminate high tyramine foods from diet) or with certain drugs *Selective serotonin reuptake inhibitors:* Irritability; gastrointestinal distress; headaches; and insomnia *Other antidepressants:* Irritability (bupropion, venlafaxine); insomnia (bupropion, venlafaxine); drug-induced seizures (bupropion, with high doses); changes in blood pressure (trazodone, venlafaxine); priapism (trazodone); sedation and sleepiness (trazodone, venlafaxine); gastrointestinal distress (venlafaxine); and headache (venlafaxine)
C. Antimanics	
Indications:	Manic episodes of bipolar disorder; unipolar depression/adjunct treatment in major depressive disorder; and behavior disorders with extreme aggression
Side effects:	Kidney abnormalities leading to increased urination and thirst; gastrointestinal distress; fine hand tremor, weakness, and ataxia; possible thyroid abnormalities (with long-term use), weight gain, and electrolyte imbalances; sedation, confusion, slurred speech, irritability, headache, and subtle cogwheel rigidity; skin abnormalities; orthostatic hypotension and pulse rate irregularities; and allergic reactions
D. Anxiolytics	
Indications:	Anxiety disorders; seizure control; night terrors; sleepwalking; insomnia and acute management of severe agitation; adjunct treatment in mania and refractory psychosis; and Tourette's disorder
Side effects:	Headache, sedation, and decreased cognitive performance; behavioral disinhibition, including overexcitement, hyperactivity, increased aggressivity, and irritability; gastrointestinal distress; central nervous system disinhibition resulting in hallucinations, psychotic-like behavior, and depression; physical and psychological dependence (particularly with long-acting benzodiazepines); rebound or withdrawal reactions (particularly with short-acting benzodiazepines); blood abnormalities; anticholinergic effects, including dry mouth, constipation, and blurred vision (antihistamines); and allergic reactions
E. Stimulants	
Indications:	Attention-deficit/hyperactivity disorder (including those with mental retardation, fragile X syndrome, Tourette's disorder, head trauma, pervasive developmental disorder, or other comorbid disorders); narcolepsy; and adjunctive treatment in refractory depression

Table 5 (continued)

Side effects:	Decreased appetite; weight loss; abdominal pain; headache, insomnia, irritability, sadness and depression; mild increases in pulse rate and blood pressure; possible temporary suppression of growth (with long-term use); choreoathetosis (pemoline) and, rarely, tic disorders; and elevated liver functions tests (pemoline)
F. Antiepileptics	
Indications:	Seizure control; bipolar disorder; adjunct treatment in major depressive disorder; and severe behavior problems (e.g., aggression and self-injury)
Side effects:	Sedation, weakness, dizziness, disturbances of coordination and vision, hallucinations, confusion, abnormal movements, nystagmus, slurred speech, and depression; blood abnormalities; gastrointestinal distress; skin rashes, alterations in pigmentation, and photosensitivity reactions; increased or decreased blood pressure and congestive heart failure; abnormalities of liver functions (sodium valproate, carbamazepine – rare); genitourinary tract dysfunction; coarsening of facial features, enlargement of the lips, gingival hyperplasia, and excessive hair growth (phenytoin); and bone marrow suppression (carbamazepine, sodium valproate)
G. Others	
Propranolol	
Indications:	Behavior disorders with severe aggression, self-injury, or agitation; Tourette's disorder; and akathisia
Side effects:	Decreased heart rate, peripheral circulation, and blood pressure; fatigue, weakness, insomnia, nightmares, dizziness, hallucinations, and mild symptoms of depression; shortness of breath and wheezing (especially in patients with asthma); gastrointestinal distress; and rebound hypertension on abrupt withdrawal
Clonidine	
Indications:	Attention-deficit/hyperactivity disorder; Tourette's disorder; behavior disorders with severe aggression, self-injury, or agitation; adjunct treatment of schizophrenia and mania; and possible use in anxiety disorders
Side effects:	Sedation; decrease in blood pressure; rebound hypertension; dry mouth; confusion (with high doses); and depression
Guanfacine	
Indications:	Attention-deficit/hyperactivity disorder and Tourette's disorder
Side effects:	Sedation (less than with clonidine); decrease in blood pressure (less than with clonidine); rebound hypertension; dry mouth; confusion (with high doses); and depression
Opioid antagonists	
Indications:	Self-injury and reversal of narcotic depression
Side effects:	Drowsiness; dizziness, dry mouth, sweating; nausea, abdominal pain; and loss of energy
Fenfluramine	
Indications:	Management of obesity and possible use in the control of some behavior problems in pervasive developmental disorder
Side effects:	Anorexia, weight loss; drowsiness, dizziness, confusion, headache, and incoordination; mood alterations, anxiety, insomnia, weakness, agitation, and slurred speech; gastrointestinal distress; increased or decreased blood pressure and palpitations; skin rashes; dry mouth; eye irritation; and muscle aches
Anticholinergics	
Indications:	Treatment of extrapyramidal reactions (dystonia, rigidity, tremor, and akathisia); sleep disorders; and agitation
Side effects:	Sedation; cognitive impairment; and anticholinergic effects, including dry mouth, constipation, and blurred vision

What we know is that they interact with various neurotransmitters, such as the catecholaminergic, indolaminergic, cholinergic, and γ-aminobutyric acid systems. It is likely that they affect both the pre- and postneuronal receptors as well as the postreceptor activity of these neurotransmitters.

5.11.7.3.2 Indications

Lithium is currently indicated for the treatment of bipolar disorder, aggression, impulsivity, and temper tantrums in children (Alessi, Naylor, Ghaziuddin, & Zubieta, 1994). The drug works reasonably well in children with behavior problems which are characterized by impulsivity, aggressiveness, rage, or emotional lability (Popper, 1995). However, clinicians are cautioned that most of this understanding comes from clinical experience and not from double-blind, placebo-controlled studies. Carbamazepine and valproic acid are indicated for bipolar disorder and as an adjunct treatment in refractory MDD.

5.11.7.3.3 Dosing and adverse effects

The recommended starting dosage for lithium ranges from 10 to 30 mg/kg in divided doses once or twice a day. Although there are no empirical data on this, Spencer et al. (1995) suggest serum levels of 0.8–1.5 $\mathrm{mEq/L^{-1}}$ for acute episodes of mania and 0.6–0.8 $\mathrm{mEq/L^{-1}}$ for maintenance therapy. The dosage and serum level needs to be individualized for optimum effectiveness. Given the approximately 18 h elimination half-life, lithium may take 5–7 days to reach steady state (Alessi et al., 1994). Daily carbamazepine dose in children ranges between 10 and 20 mg/kg, given twice a day. The recommended starting dose of valproic acid is 15 mg/kg/day, which can be gradually titrated up to 60 mg/kg/day, given three times a daily.

The side effects of the antimanics are presented in Table 5.

5.11.7.4 Anxiolytics

The anxiolytics are used to treat pathological anxiety states. Two general classes of drugs, antidepressants (mainly the tricyclics and the MAOIs) and the antianxiety agents (most notably the benzodiazepines), are used to treat the various anxiety disorders seen in children (e.g., separation anxiety disorder, panic disorder, agoraphobia, school phobia, and generalized anxiety disorder). The benzodiazepines are also known as sedative-hypnotics because they act as hypnotics in high doses, as anxiolytics at moderate doses, and as sedatives in low doses. In general, the sedatives reduce daytime activity, temper excitement, and generally calm the child, and hypnotics produce drowsiness and facilitate the onset and maintenance of sleep. The following benzodiazepine drugs are currently labeled as antianxiety agents for use in the United States: chlordiazepoxide (Librium); clorazepate (Tranxene); diazepam (Valium); lorazepam (Ativan); oxazepam (Serax); prazepam (Centrax); halazepam (Paxipam); and alprazolam (Xanax). Flurazepam (Dalmante) and temazepam (Restoril) are two other benzodiazepine drugs but these are marketed for insomnia. Buspirone, a nonbenzodiazepine anxiolytic, is an azaspirodecanedione that lacks sedative, anticonvulsant, or muscle relaxant properties.

5.11.7.4.1 Mechanism of action

The benzodiazepines are closely associated with γ-aminobutyric acid (GABA), the most prevalent inhibitory neurotransmitter system in the brain (Zorumski & Isenberg, 1991). The recognition sites for GABA are coupled to chloride ion channels, and when GABA binds to its receptors, these channels open, thereby increasing the flow of chloride ions into the neurons. There are two subtypes of central nervous system benzodiazepine receptors, BZ_1 and BZ_2. The BZ_1 receptors are involved in the mediation of sleep, and the BZ_2 receptors are involved in cognition, memory, and motor control. Theoretically, a benzodiazepine hypnotic can have more affinity for one or the other receptor, thereby producing differential response.

The mechanism of action of buspirone does not involve interaction with a benzodiazepine-GABA receptor. It interacts with presynaptic dopamine receptors and with postsynaptic 5-HT_{1A} (serotonin) receptors, for which it is a partial agonist. However, despite its affinity for dopamine receptors, buspirone is not a neuroleptic and it does not have adverse effects or risk profile of neuroleptics.

5.11.7.4.2 Indications

The high-potency benzodiazepines (e.g., clonazepam [Klonopin], alprazolam [Xanax], lorazepam [Ativan]) are used in the treatment of anxiety disorders, as an adjunct in the treatment of refractory psychosis and mania, severe agitation, Tourette's disorder, severe insomnia, and major depressive disorder with anxiety. The atypical anxiolytic, buspirone (BuSpar), is also used for anxiety disorders and as an adjunct in the treatment of refractory OCD. It is also used for treating aggressive behaviors in children with mental retardation and autism.

5.11.7.4.3 Dosing and adverse effects

The recommended dosage for the long-acting, high-potency benzodiazepine (i.e., clonazepam) is a one to three times a day administration of a total daily dose of 0.01–0.04 mg/kg (Spencer et al., 1995). The short-/intermediate-acting, high-potency benzodiazepines are given three to four times a day because they present a higher risk for rebound and withdrawal reactions. In terms of total daily doses, alprazolam is 0.02–0.06 mg/kg, lorazepam is 0.04–0.09 mg/kg, and oxazepam is 0.05–1.7 mg/kg (Spencer et al., 1995). The total daily dose of buspirone ranges from 0.3 to 0.6 mg/kg.

The side effects of the anxiolytics are presented in Table 5.

5.11.7.5 Stimulants

Stimulants are probably the most widely used psychotropic drugs with children. They are sympathomimetic drugs that are structurally similar to the endogenous catecholamines. The most commonly used stimulants include dextroamphetamine (Dexedrine), methylphenidate (Ritalin), and magnesium pemoline (Cylert).

5.11.7.5.1 Mechanism of action

The stimulants act in the central as well as in the peripheral nervous system by blocking the reuptake of catecholamines into the presynaptic nerve endings and by blocking degradation of the nerve endings by the monamine oxidase enzyme. It is likely that each of the stimulants has a distinct mode of action and therefore have differential clinical effects. Indeed, the precise mechanism of action of these compounds is still poorly understood.

5.11.7.5.2 Indications

The stimulants are indicated for ADHD, ADHD with comorbid disorders, ADHD in children with developmental disabilities, and as adjunctive therapy for refractory depression. Generally, stimulants are effective in controlling the symptoms of ADHD, especially hyperactivity, impulsivity, distraction, and inattention (Barkley, DuPaul, & Costello, 1993). Further, they are effective in improving parent–child interactions, peer relationships, academic productivity, and classroom behavior (Barkley, 1990). However, academic achievement is minimally affected by the stimulants but they do enhance performance on measures of vigilance, impulse control, fine motor coordination, and reaction time.

5.11.7.5.3 Dosing and adverse effects

For the short-acting stimulants, the recommended daily dosage is 0.3–1.5 mg/kg for dextroamphetamine and 1.0–2.0 mg/kg for methylphenidate. The onset of action for these compounds is within 30–60 min, with peak clinical effect being evident for up to three hours. The longer-acting magnesium pemoline is given in a single daily dose of 1–3 mg/kg. At therapeutic doses, the onset of action for this drug is very rapid, producing a clinical response almost immediately. Generally, the stimulants are given with or after meals because of their anorexigenic effects. Because of increased risk of liver toxicity with pemoline, it is generally not considered a first-line stimulant medication.

The side effects of the stimulants are presented in Table 5.

5.11.7.6 Antiepileptics

There is increasing indication that carbamazepine, clonazepam, and valproic acid are being used alone and in combination with standard psychotropic medications to treat adults with various psychiatric disorders, such as mania, depression, treatment-resistent or atypical panic disorder, and bulimia, among others (Post, 1987). As discussed in Section, Au:X-ref.OK?, carbamazepine and valproic acid are used as alternative mood-stabilizing antimanic agents in children with bipolar disorders. Case reports and uncontrolled trials suggest that carbamazepine may be useful in treating ADHD, intermittent explosive disorder, aggressive disorders, conduct disorder, and some mood disorders in children (Carpenter & Vining, 1993). However, there are few well-controlled studies attesting to the efficacy of carbamazepine in childhood disorders (Evans, Clay, & Gualtieri, 1987; Remschmidt, 1976), and it has not been approved by the Food and Drug Administration for neuropsychiatric indications in children.

Antiepileptics have a history of use in the developmental disabilities, especially for controlling intractable behavior problems. The primary psychiatric use of antiepileptics in children with developmental disabilities is for affective disorders, such as mania, bipolar disorder, or schizoaffective disorder, particularly if these disturbances have been resistant to standard psychotropic medication. Early studies strongly suggested that phenytoin (Dilantin) may have some behavioral effects on individuals with developmental disabilities, but these claims have not been validated in well-controlled studies (see Aman & Singh, 1991). Carbamazepine, valproic acid, and, to a much lesser extent, clonazepam are currently being used for this purpose (Ellis et al., 1997). Much remains to be done with regard to establishing the efficacy of the antiepileptics in childhood psychiatric disorders, their mechanism(s) of action, dosage, and adverse effects.

5.11.8 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

It is clear that we have come far since Bradley's serendipitous finding of the effects of benzedrine on the behavior of children. For several decades, psychopharmacology of childhood disorders was a neglected area of clinical practice because of a lack of knowledge. Research in the field was almost nonexistent because of a shortage of well-trained researchers as well as a lack of adequate scientific methodologies for studying drug effects in children. Indeed, for many decades, our information on drugs and dosage was derived from the adult literature even though we knew that children are not miniature adults. Indeed, studies showing that, unlike adults, adolescents do not reliably respond better to tricyclic antidepressants than to placebo attests to the fact that we cannot ever again assume that the clinical and research findings with adults will also be true for adolescents. That this assumption is passé has been endorsed by the FDA which now requires that all drugs intended for children to be tested with children so that the effects of these drugs and dosages can be appropriately determined.

Since the mid-1980s, child and adolescent psychopharmacology has achieved the status of a field worthy of scientific study in its own right. Yet much remains to be achieved. In general, virtually every area of psychopharmacology of childhood disorders needs further research. Indeed, we know so very little about the pharmacokinetics and pharmacodynamics of most major psychoactive medications as they pertain to children. Because developmental factors play such an important role in the outcome of pharmacotherapy, we need research that takes into account the interaction between the child's developmental level, environment, and different classes of drugs.

As for pharmacogenetics, we know little about the effects of hereditary factors on drug response with regard to adult populations and almost nothing in children (Nebert & Weber, 1990). For example, most of our knowledge of drug effects is with white populations, yet the majority of the world's population is of other ethnic origins and there is very little data on the interaction between ethnicity and psychotropic drugs. Current research strongly suggests that, at least in adults, ethnicity accounts for some of the interindividual variations in drug response to many psychotropic and other drugs (Lin, Poland, & Nakasaki, 1993). It is timely for us to consider ethnic differences in pharmacokinetics and pharmacodynamics in child populations. Other factors that impact drug outcome, such as compliance and placebo effects, are also influenced by cultural beliefs and expectations. Because these sociocultural determinants of treatment outcome are also an important factor in psychological therapy, this provides clinical psychologists a unique opportunity to study the effects of these variables in both psychological and psychopharmacologic treatment.

A majority of children with mental health problems have comorbid psychiatric disorders (Achenbach, 1991b). Comorbidity presents interesting challenges to clinicians because not only does it have important implications for pharmacologic treatment, it also has implications for other therapies. Of interest is the use of targeted combined psychotropic drugs for comorbid disorders in children. While we have traditionally eschewed the use of polypharmacy, especially intraclass polypharmacy, our current thinking is that there is indeed a place for combined psychotropic treatments. However, much of this thinking is based on clinical experience and not on well-controlled outcome studies. Further, given that psychopharmacologic treatment is only one component of a treatment regimen that includes psychosocial as well as educational intervention, more research is needed to assess the individual, combined, and interactive effects of these treatments.

In terms of clinical practice, there has been growing interest in individualizing care within standardized treatment protocols. For example, clinicians and researchers have been developing psychopharmacologic treatment algorithms for the various childhood disorders (Vitiello, 1997; Walkup, 1995). These algorithms are based mainly on our clinical experience and take into account children with comorbid disorders as well as interindividual variations in drug response. Because these algorithms have been developed on the basis of global characteristics of children with specific disorders, it assumes that the physician will use good clinical judgement with individual cases based on thorough baseline assessments. Further, because these algorithms are multistep procedures, an empirical evaluation of a particular algorithm for a specific disorder will necessitate the evaluation of the entire algorithm rather than its component steps. This is an exciting development in child psychopharmacology as it integrates clinical practice and research, where the clinical concerns of the child drives the research protocol.

5.11.9 SUMMARY

Psychopharmacology of childhood disorders is a growing area of clinical practice and research. For most of its 60 years, childhood psychopharmacology has played second fiddle to adult psychopharmacology but this is rapidly changing. The biological revolution has affected both child and adult psychiatry equally. Further, experimental and clinical psychologists have brought to this field useful research methodologies that have anchored psychopharmacological research in the context of the child's life rather than just on the child's biology. However, much of our current knowledge is still based on experience rather than on science. While child psychopharmacology is both a science and an art, we are well short on the science.

5.12.1 INTRODUCTION

The past decade has seen rapid developments in the area of prevention of psychopathology. Mental health policymakers and planners have gradually come to recognize the value of prevention rather than intervention after problems have become well established. The prevention of psychological problems is typically emphasized as a target of many mental health policies across the world (Spence, 1996a). The increased focus upon prevention is reflected in the numerous published studies that describe preventive programs in many parts of the world. The literature reveals a wide spectrum of preventive efforts, ranging from generic attempts to enhance psychological well-being to those that focus on prevention of specific psychological disorders or a particular high-risk group. Nevertheless, the funds spent by health care providers on prevention of psychopathology represent a very small proportion of the total mental health budget (Mrazek & Haggerty, 1994; Spence, 1996a). In consequence, the vast majority of mental health professionals focus their work upon the treatment of existing psychopathology, rather than upon its prevention.

There are many reasons why prevention of psychopathology makes sense. Although estimates vary considerably, epidemiological studies suggest that, in any given year, around 20–30% of adults (Robins & Regier, 1991) and 10–15% of children and adolescents (Department of Health and Human Services, 1991; Institute of Medicine, 1989) will exhibit a psychological problem of sufficient magnitude to interfere significantly in daily functioning and that meets diagnostic criteria for a clinical disorder. The cost to the community of psychological disorders is enormous. For example, in 1993 the cost of psychological disorders in Australia (with a population of around 17 million) was estimated as being between A$3 and A$6 billion per annum (Human Rights and Equal Opportunity Commission, 1993, p. 835). This figure included the cost of consultations with mental health professionals, hospitalization, medications, housing, and pension payments. Estimating the annual cost of mental illness, drug and alcohol abuse in the USA for 1990, Eisenberg (1995) and Mrazek and Haggerty (1994) cite evidence to suggest an overall cost to the community of US$212 billion. Thus, successful prevention of mental health problems would produce huge economic savings to the community, over and above the obvious benefits of reduced personal suffering.

5.12.2 APPROACHES TO PREVENTION

Before proceeding, it is important to discuss the various approaches to prevention and the terminology used to describe these methods. Traditionally, three levels of prevention were described, namely primary, secondary, and tertiary (Caplan, 1964). The first level of primary prevention referred to efforts to reduce the incidence of new cases through intervention before disorders occur. Secondary prevention referred to interventions that aimed to reduce the prevalence of disorders through early identification of established cases. Tertiary prevention referred to efforts to reduce the duration and degree of disability associated with an existing disorder, through treatment and prevention of relapse.

The disadvantage of the primary, secondary, and tertiary distinction was that it could be said that secondary and tertiary levels related more to treatment than to prevention. Only the primary level related specifically to intervention prior to the development of a disorder, but the term provided minimal information about the type of intervention being used. More recently, the prevention literature adopted an alternative approach to classifying preventive efforts that provides more detail about the type of prevention approach (Gordon, 1987). Gordon proposed three types of preventive approaches based on the presence and extent of risk factors related to the development of the disorder of concern among individuals who did not already manifest a disorder. These approaches were labeled universal, selective, and indicated. Universal preventive interventions are those that are provided to entire populations. Selective prevention is targeted to those individuals who are members of a group, the membership of which places them at increased risk for the development of a mental disorders. Indicated prevention focuses on asymptomatic but high-risk individuals who are found to manifest a risk factor, condition, or abnormality that identifies them as being at high risk for the future development of psychopathology (Gordon, 1987).

Although the universal, selective, and indicated distinction represented an advance upon the primary, secondary, and tertiary approach, this method of categorization is still subject to criticism. Such an approach assumes that psychological disorders are discrete, present–absent phenomena. In reality, most forms of psychopathology lie on a continuum from mild or few symptoms to more severe and/or numerous symptoms. The decision to classify a person as experiencing a mental disorder depends on meeting some arbitrary cut-off for the number and severity of symptoms. Furthermore, early, mild symptomatology is a risk factor for later development of many forms of psychopathology. For example, conduct disorder in young people tends to develop along a trajectory in which early symptoms are predictive of later development of more severe symptomatology (Farrington, 1995). Once on this trajectory, many children show increasing levels of symptomatology with increasing age. Thus, indicated prevention must also target those individuals who show early, mild symptomatology that represents a risk factor for later development of a more serious psychological disorder. Any method of categorizing preventive interventions needs to take into account the continuum of psychological difficulties and the trajectory in the development of many disorders. Implicit in Gordon's (1987) approach to prevention is the assumption that evidence is available regarding risk factors for the development of mental disorders. Risk factors refer to biological, environmental, and psychological factors that increase the probability of development of a psychological problem. Effective prevention requires not only that we are able to identify risk factors for particular forms of psychopathology, but also that we have reliable and valid methods of identifying those individuals who manifest these risk features and that we have effective means of altering these variables. As described below, there is now considerable evidence regarding those factors that increase the risk of development of psychological problems. Similarly, evidence has shown that many of these variables can be changed effectively.

One further development that should be mentioned in the area of prevention is the focus not only on identification and alteration of risk variables but also on protective factors. Protective factors refer to those variables that produce a resilience to the development of psychological difficulties in the face of adverse risk factors. Clearly there are many young people who emerge from the face of adversity relatively well-adjusted and unaffected by the risk factors to which they have been exposed. Increasingly, research has focused on identifying variables associated with resilience which buffer the impact of risk factors. This shift in emphasis is important, as there are many risk factors that cannot be easily altered or removed, and an alternative or additional strategy for prevention is to build up protective factors.

5.12.3 RISK FACTORS

Efforts to identify causal factors relating to the development of child and adolescent psychopathology have yielded a great deal of information concerning risk and protective factors. This knowledge has emerged from longitudinal studies that allow us to entangle some of the interrelationships between psychopathology and the myriad of correlated variables that are associated with psychological disorders. Although we are a long way from fully understanding the etiological factors in child psychopathology, the evidence is sufficiently well developed to allow us to draw some tentative conclusions. These points are discussed in more detail below but can be summarized as follows:

(i) It is clear that child psychopathology results from a complex interaction of numerous environmental and intrinsic child variables.

(ii) There are many different sources of influence and no one factor is sufficient to account for any specific emotional and behavioral disorder.

(iii) Risk factors appear to have a multiplicative, not just additive effect so that the probability of developing a behavioral or emotional disorder increases considerably as the number of risk factors affecting a child increases.

(iv) Some risk factors are common to a wide range of emotional and behavioral disorders, whereas others have a more specific influence upon particular forms of psychopathology.

5.12.3.1 Genetic and Biological Factors

It is well established that parents with psychopathology are more likely than parents without psychopathology to have children who exhibit emotional and behavioral problems. Similarly, children with psychiatric disorders are more likely than their well-adjusted peers to have parents who meet diagnostic criteria for a mental disorder. These familial factors hold for internalizing and externalizing disorders alike (Rutter et al., 1990). However, such results tell us little about the relative contribution of genetic and family environmental factors to the development of psychopathology. Parental psychopathology is frequently associated with greater family stress, financial difficulties, marital discord, and poor parenting skills. Thus, in addition to genetic contributions, we must also consider the environmental influences that accompany parental psychopathology. Although strong familial associations are evident for childhood depression, anxiety, conduct disorder, and attention deficit disorder, the evidence has not yet clarified the degree to which these reflect genetic or environmental influences (Rutter et al.). It is only for disorders such as autism, multiple tics, Tourette's syndrome, bipolar disorder, and schizophrenia that strong genetic influences have been clearly established.

Research into the heritability of disorders such as depression, anxiety, and disruptive behavior problems have produced more conflicting results. Where genetic influences have been implicated for these disorders, it appears that heritability relates to a genetic predisposition to develop a range of psychological problems, rather than the heritability of a specific disorder such as anxiety or depression. Furthermore, where strong heritability influences have been found, it is not clear what is inherited. For example, it is possible that children inherit a particular temperament style or other intrinsic characteristics (e.g., learning disability) that predisposes them to develop a range of psychological problems.

In addition to genetic influences, there are a range of biological factors that are associated with increased prevalence of child psychopathology. These include prenatal, birth, and early childhood influences, such as poor prenatal health care (including smoking and drug–alcohol abuse), preterm delivery, birth delivery complications, and toxins. Again the mechanism of action of these biological variables is unclear. It is possible that these biological factors impact upon child psychopathology through their role in the development of learning disabilities, or irritable, difficult temperament style. Alternatively, it is possible that the crucial variables associated with the development of child psychopathology are correlates of the biological factors, rather than biological factors *per se*. For example, it is feasible that parents who engage in high-risk prenatal behaviors, and who are therefore at greater risk of premature births, are more likely to be those parents who subsequently show poor parenting skills. Thus, the causal factor in the development of child psychopathology could be poor parenting skills rather than premature birth. Researchers are still in the process of unraveling these complex causal relationships.

Although the evidence indicates genetic and biological influences upon many forms of child psychopathology, it is important to note that many children with a strong family history of mental disorder or exposure to biological risk factors do not proceed to develop psychopathology. Similarly, many children without a family history of psychopathology or exposure to biological trauma do develop emotional and behavioral disorders. Thus, we need to examine the other characteristics of family environments and individuals that may increase or decrease the risk of developing child psychopathology.

5.12.3.2 Family Environment

There are many family environment factors that increase the chance of developing emotional or behavioral problems. Many of these factors appear to increase the chance of developing a wide variety of psychological disorders, rather than any one form of psychopathology. This may explain the high level of comorbidity between behavioral disorders of children and adolescents. For example, one of the most frequently noted correlates of many forms of child psychopathology is socioeconomic disadvantage. However, in trying to identify risk factors, it is often difficult to determine whether a particular variable has a direct effect upon the development of psychological problems or is simply correlated with some other variable that impacts upon psychopathology. We know that socioeconomic disadvantage is associated with many factors such as poor housing conditions, poor educational resources, unemployment, single-parent status, increased financial stress, parental psychopathology (particularly depression and drug–alcohol abuse), residential areas with increased crime rates and impoverished social and recreational facilities. These variables are, in turn, all associated with elevated rates of child psychopathology (Dodge, Pettit, & Bates, 1994). Efforts to control for these variables in longitudinal research suggest that economic disadvantage, unemployment and single–parent status while being correlates of child psychopathology may not have direct effects. Rather, evidence suggests that factors such as parental psychopathology and poor parenting skills are likely to be the mechanism through which societal factors have their influence upon emotional and behavioral problems of childhood (Dodge et al., 1994; Patterson, 1996). Thus, many children from poor, unemployed, or single-parent families may emerge as relatively well-adjusted young people if the parents are mentally healthy and have strong parenting skills.

Parental anxiety, depression, and alcohol abuse have been shown to be associated with a range of child and adolescent mental health problems (Rutter et al., 1990). Typically, the association between these forms of parent disorder and child psychopathology is not limited to a specific disorder across generations. Rather, parental anxiety, depression, and substance abuse is linked to a range of psychological problems in the offspring. It is important, therefore, that we determine the mechanisms through which parental psychopathology has its action. There is a complex interrelationship between the factors of parental psychopathology, marital discord, lack of partner support, divorce and separation, single-parent status, increased exposure to life stressors (e.g., financial hardship), poor parenting skills, and negative patterns of communication within the family. All these variables have been identified as risk factors for the development of child psychopathology (Mrazek & Haggerty, 1994; Spence, 1996a). It is difficult to tease apart these interrelationships. Parental psychopathology is likely to increase marital difficulties, and similarly marital problems may increase disorders such as depression, anxiety, and substance abuse. Effective parenting is likely to decline when parents experience emotional problems, and the rate of negative communications between parents and children is likely to increase (Dadds, in press). Marital conflict may lead to divorce and separation, and the financial and emotional stress that frequently accompanies single-parent status. Such stressors place an additional strain upon effective parenting, and may also exacerbate parental psychopathology. Overall, a complex interplay between risk factors operates to increase the chance that a child will develop psychological difficulties. Evidence suggests that the crucial variables in this network are the parenting skills and communication patterns between parent and child which play a mediating role in determining the influence of parental psychopathology upon child behavior problems (Harnish et al., 1995).

The variables of poor parenting skills and negative family communication patterns have been associated with a range of child and adolescent problems, including conduct disorder (Dadds, in press), depression (Kaslow & Racusin, 1994), attention deficit disorder (Barkley, 1989), and anxiety disorders (Dadds, Barrett, & Rapee, 1996). For some families, poor parenting skills and negative communication patterns may reflect long-term skill deficits, rather than a response to life circumstances. In either case, preventive interventions should ensure the development and use of effective parenting skills and positive family communication patterns. It is important to note, however, that the direction of causality is not always a simple one in which aversive parental communication patterns cause problematic child behavior. There is some evidence that the relationship may be a reciprocal one in which difficult child behavior may trigger negative parenting responses (Barkley, 1989). Thus we need to take into account the reciprocal nature of influences between parent and child behavior.

Much of the research relating to parental behavior and child psychopathology has focused upon the development of conduct disorder. However, recent studies have also demonstrated that parental behavior is probably an important contributing factor in the development of children's anxiety and depression (Sanders, Dadds, & Barrett, 1995). To date, these studies have been cross-sectional or have involved retrospective reports from anxious or depressed adults about their parent's behavior. Thus, it is not possible to draw firm conclusions about the direction of causality. However, the evidence points towards a significant role of parental factors in the development of childhood anxiety and depression. Rapee (1997), in a recent review of the literature, concluded that anxiety in children was associated with overcontrolling/overprotective parenting styles which inhibit the development of problem-solving skills in children and limits their developing sense of self efficacy. Faced with stressful or novel situations, these children are then more likely to experience anxiety. In contrast, Rapee (1997) concluded that depression in children is associated with excessively critical and negative communications from parents.

5.12.3.3 Negative Life Events

There have been many studies investigating the impact of negative and traumatic life events in children. The results have tended to produce conflicting findings. Generally, the evidence suggests that higher rates of emotional and behavioral difficulties are associated with exposure to major negative life events (Goodyer & Altham, 1991). However, many young people who experience major trauma, such as death of a parent, family break up, war, and disasters, do not go on to develop clinically significant psychopathology. For example, children vary markedly in their adjustment following parental divorce, with many children coping well with the transition (Amata & Keith, 1991; Forehand, 1992). In contrast, some children experience considerable adjustment problems, particularly if the postdivorce environment is characterized by ongoing fighting between parents (Hess & Camara, 1979). Thus, negative life events clearly do not, on their own, provide an adequate explanation for the development of child psychopathology. Rather, it appears that the impact of negative life events depends on the characteristics of the child and the additional impact of other negative environmental factors. Furthermore, we need to understand more about the mechanisms and processes through which negative life events influence child psychopathology. Factors which appear to reduce the negative impact of aversive life events on children include social support and problem-focused coping strategies of the child (Compas, 1987). We also need to consider the impact of negative life events, such as parental divorce or death of a parent, upon the parenting style of the major caretaker. Traumatic life events may set in place a sequence of changes which culminate in ineffective parenting behavior and impaired family communication patterns. Thus, the relationship between negative life events and child psychopathology may be mediated by parenting behavior of the child's caretaker. There is some evidence to support this proposition from studies of children who experience significant trauma. McFarlane (1987) demonstrated that a strong predictor of children's adjustment following a severe bushfire was the mother's level of overprotective parenting.

In some instances, factors may interact to exacerbate or trigger the negative impact of adverse life events. For example Rutter (1987) described the interaction effect of maternal loss combined with other major, negative life events. Maternal loss on its own did not produce an increased risk of psychopathology, but when combined with some other major negative life event, the combined factors produced a threefold increase in the chance of developing depression, far exceeding the impact of major negative life events alone. These results also demonstrated the delayed impact of maternal loss, in that this factor created vulnerability to psychiatric disorder only later in life and only when combined with other direct risk variables.

5.12.3.4 Intrinsic Child Characteristics

In addition to the environmental risk factors of child psychopathology, it is important to consider the intrinsic characteristics of the child that place him or her at greater risk (Coie et al., 1993). Child temperament and intellectual functioning have been shown in many studies to be risk factors for the development of child psychopathology. An early childhood temperament characterized by irritability, high levels of crying, irregular sleep, and eating problems is predictive of externalizing behavior problems in later childhood (Prior, 1992). Temperament influences can also be identified for internalizing disorders. The work of Kagan and colleagues (Kagan, Reznick, & Gibbons, 1989; Kagan & Snidman, 1991) has been influential in identifying a relatively stable temperament style which they term "behavioral inhibition." The characteristic features of behavioral inhibition include initial timidity, shyness, withdrawal, distress, and emotional restraint when exposed to unfamiliar people, places, or contexts (Asendorpf, 1993). This behavioral pattern is associated with elevated physiological indices of arousal and has been shown to have a strong genetic component (Plomin & Stocker, 1989). Children who show a stable temperament style of behavioral inhibition are more likely to develop anxious behavior and anxiety disorders during childhood (Biederman et al., 1993; Hirshfeld et al., 1992; Rosenbaum et al., 1993).

Although the evidence points to a significant contribution of early childhood temperament to the development of psychopathology, Prior (1992) pointed out that not all children who show these temperament patterns will progress to show behavioral difficulties later in childhood. Thus, we need to explain how childhood temperament interacts with other personal and environmental characteristics to determine the occurrence of psychopathology. In particular, it is important to identify those parenting patterns which buffer the impact of a difficult early childhood temperament and those parenting factors which may exacerbate the influence of high-risk temperament characteristics.

Low IQ and learning difficulties have also been linked to the greater prevalence of a wide range of emotional and behavioral problems in children, including conduct disorder, attention deficit–hyperactivity disorder, and depression (Farrington, 1995). The mechanisms by which low IQ and learning difficulties have an impact upon psychopathology is unclear. It is possible that school failure and negative school experiences set in train a trajectory towards conduct problems, low self-esteem, and depression. Alternatively, the biological factors that underlie low IQ and learning difficulties could also be responsible for attention problems, impulsivity and "difficult" temperament for some children. A further possible explanation could lie in heritable characteristics through which the parents of children who have low IQ and learning problems may have restricted cognitive abilities and consequently poor parenting skills. Much more research is needed to determine the mechanisms by which low IQ and learning difficulties impact upon child psychopathology. Meanwhile, these variables should be regarded as risk factors towards which preventive interventions should be directed.

Children's cognitive style is a further intrinsic child characteristic that has been found to predict later psychopathology, with particular patterns and styles being associated with specific forms of psychopathology. For example, a pessimistic cognitive style for interpreting information has been shown to predict later depression in children (Jaycox, Reivich, Gillham, & Seligman, 1994). Although longitudinal studies have yet to be completed, cross-sectional studies have shown an association between a cognitive style characterized by increased attention to and interpretation of threat stimuli among clinically anxious children (Kendall, 1991). Similarly, aggressive children are characterized by a bias towards processing information in a confronting and threatening manner (Lochman & Dodge, 1994).

Early childhood behaviors that represent mild symptomatology have also been found to significantly predict later clinical levels of psychopathology. For example, many studies have shown that early aggressive behavior is the best single predictor of risk for later aggression and delinquency (Guerra, Huesmann, Tolan, & Van Acker, 1995; Loeber, 1990). Therefore, within the "high-risk" category of young people to whom preventive interventions could be directed, we must include children who show early behavior problems.

To summarize, there are clearly a wide range of environmental and intrinsic child characteristics that interact as risk factors to increase the chance of developing emotional and behavioral problems. The challenge for researchers is how to identify clusters of risk factors that collectively increase the chance of the development of psychological problems. Kazdin and Kagan (1994) pointed out that individual risk factors may have only a minimal effect on their own, but may have a multiplicative, interactive influence upon psychopathology. It is also important to determine why some individuals who experience particular risk factors do not progress to show psychological difficulties. For example, not all children who manifest a stable temperament of behavioral inhibition proceed to develop an anxiety disorder. Similarly, not all children who show a "difficult" irritable early temperament style go on to show disruptive behavior problems. Thus, it is likely that certain childhood temperaments interact with particular parenting practices to increase the chance of psychological difficulties. In the case of children with a temperament style of behavioral inhibition, it may be only those children whose parents are overprotective and overcontrolling who go on to show anxiety problems. Those initially behaviorally inhibited youngsters whose parents encourage them to experience new situations, and who model a calm, problem-focused coping style, may be less likely to show anxious, fearful behavior as they grow older (Spencer, 1996b). Therefore, future research needs to clarify the way in which risk factors interact to elevate the risk of developing child psychopathology.

5.12.4 PROTECTIVE FACTORS

Although we now have a great deal of knowledge concerning the risk factors for the development of psychopathology, many of these factors are extremely hard to change. High levels of family stress, bereavements, family break-ups, parental psychopathology, single-parent status, and socioeconomic disadvantage, while important targets for reduction, are likely to continue to occur with relatively high frequency in our communities. Thus, it is important to identify those factors that protect children from the adverse consequences of such risk factors. We do know that many children emerge from high-risk environments without showing emotional and behavioral disorders. However, only recently have researchers started to investigate systematically those protective influences that produce a resilience against adverse risk factors. Moreover, Rutter (1987) discussed confusion within the literature regarding what is meant by protective or resilience factors. He pointed out that many of the variables that had been proposed as protective factors merely represented the opposite end of continuum of a risk factor. For example, generally a high level of parenting skills, high intellectual functioning, and high socioeconomic status have been found to be associated with low levels of risk. Rutter proposed that protective factors do not refer to these opposite poles of risk factors, but rather they relate to variables that reduce the impact of a risk factor upon the development of psychopathology, instead of or in addition to having a direct effect of its own. Protective factors also include events which produce a turning point in a trajectory in the development of psychopathology towards a more adaptive long-term outcome.

Although the research is in its infancy, we can make some tentative suggestions about protective factors. Within the family, secure and harmonious parent–child relationships, social support from elders and peers, and a structured, coherent family environment have been shown to buffer the negative impact of social adversity (Rutter, 1987). Parental supervision and regulation of childrens' peer group activities outside the home have also been identified as factors that reduce the risk of delinquency for children reared in a high-risk environment (Patterson & Stouthamer-Loeber, 1984).

There are also intrinsic child characteristics that appear to serve a protective function against the development of a wide variety of emotional and behavioral problems. These include positive self-concept and a range of skills (problem solving, planning, skills to remove oneself from the risk environment, social skills), and academic success (Rutter, 1987; Werner, 1987). In a recent study, O'Donnell, Hawkins, and Abbott (1995) identified several factors that appeared to inhibit the risk of subsequent involvement in serious delinquency in a sample of boys who were identified as aggressive by teacher report at ages 10–11 years. Measures were taken at ages 12–13 years of prosocial skills, school achievement and bonding, norms against substance abuse, and interaction with adults and peers who were involved in antisocial behavior. These factors significantly discriminated between boys who were and were not involved in serious delinquent behavior one year later.

If we are able to identify protective factors, it is important that we examine the processes through which these variables modify the impact of risk factors. Again, the research is in its infancy, but we can speculate about likely mechanisms. For example, Rutter (1987) reported that children with "easy" temperaments are less likely to be scapegoated or become the targets for parental criticism and negative communication, thereby reducing the negative impact of risk factors such as parental depression or marital discord. Similarly, adolescents with strong planning skills were less likely to have teenage pregnancies nor to enter into marriage with a dysfunctional partner, thereby reducing the negative impact of early institutional care (Rutter, 1987). We can also speculate that children with good social skills are more likely to develop positive relationships with supportive parents, teachers, and peers, providing a buffer against a range of risk factors.

5.12.5 IMPLICATIONS FOR PREVENTION

Our knowledge regarding risk and protective factors for the development of psychopathology provides an indication as to the variables that should be targeted in preventive interventions. Effective prevention of child psychopathology requires not only that we are aware of risk and protective factors, but that effective methods are available for producing change in these variables. The evidence regarding risk and protective factors suggests that there are some variables that impact upon the development of a wide range of emotional and behavioral problems. However, many of these factors are difficult to change. For example, current technology does not permit alteration of genetic influences. Similarly, many children in our society will continue to be exposed to situations that place them at increased risk of psychopathology, such as parental mental illness, divorce, abuse, marital conflict, death of a parent, and other negative life events. Although an important goal for prevention is to reduce children's exposure to such high-risk situations, inevitably a significant number of children will still experience these adverse life circumstances. For these children, the aim of prevention must be to reduce the impact of risk factors by increasing childrens' coping skills and enhancing parenting skills.

There are many practical difficulties that lie in the way of the implementation of preventive programs. Frequently the families who could most benefit from preventive interventions are those who are most difficult to access in terms of willingness and ability to participate in the program. The children most at risk are likely to be living within impoverished life circumstances or within families who are experiencing significant stress (e.g., parental psychopathology, bereavements, single-parent status, and family break-up). The evidence reviewed above suggests that two crucial factors that mediate the impact of environmental risk factors upon many forms of child psychopathology are parenting skills and parent–child communication patterns. Thus, it makes sense to suggest that training in parenting and family communication skills should be fundamental components of effective prevention. One of the goals of preventive programs must therefore be to identify ways of engaging parents from high-risk groups. The evidence also suggests that there are a range of intrinsic child variables that may mediate or moderate the impact of risk factors in the development of child psychopathology. A further approach to prevention may therefore be to focus on the development of protective factors in children. For example, programs could focus on the teaching of problem solving, planning, social, coping, and academic skills, all of which have been identified as protective factors. Similarly, it may be feasible to develop positive, supportive social networks with other key adults in the child's life, as a further protective factor.

The evidence regarding risk factors also suggested that the probability of developing psychological problems increases markedly as the number of risk factors increased. Indeed, there is some indication that this is not simply an additive effect, but rather the probability of developing psychopathology increases multiplicatively with increasing numbers of risk factors (Coie et al., 1993). This suggests that children most at risk will be those who experience multiple risk factors. Policymakers and mental health planners need to decide where best to invest funds in preventive programs. So far, there are many unanswered questions.

(i) Is it more cost-effective to focus preventive efforts on the few children with multiple risk factors, or upon a larger number of children with only one or two risk factors?

(ii) For children with multiple risk factors, are intensive interventions that tackle multiple etiologies required in order to prevent psychopathology, or can prevention with these children be achieved by tackling only one or two risk or preventive factors?

(iii) Should children be singled out for prevention programs through some process of assessment or identification, or should prevention be applied to whole populations in order to avoid specific targeting and potential effects of labeling?

(iv) Should preventive funds be invested in efforts to minimize one single disorder or, given the many common etiologies across disorders, into broad-spectrum projects that aim to prevent multiple forms of psychopathology?

(v) Are prevention programs best geared towards efforts to minimize environmental risk factors, or to providing children with the skills to cope with adverse life circumstances?

(vi) To which age group should preventive efforts be directed; to older children who are more able to understand the concepts being taught, or to younger children who have been exposed to risk factors for a shorter period of time?

Certainly, there are more questions than answers.

5.12.6 THE EFFECTIVENESS OF PREVENTIVE PROGRAMS

Prevention programs come in many forms and evaluative studies have suffered from a wide range of methodological limitations, making it difficult to draw general conclusions about their effectiveness. Some programs have taken a broad population approach, whereas others have targeted a specific high-risk group. The goal of prevention for some interventions has been general enhancement of mental health, whereas others have aimed to prevent some specific disorder. It is beyond the scope of this chapter to provide extensive descriptions of the many preventive interventions that have been reported in the literature and interested readers are referred to Mrazek and Haggerty (1994) for a more detailed review. What follows is a summary of some of the major preventive studies, as a means of illustrating some of the key points within the prevention area. In keeping with current methods of categorization, the following review will divide preventive interventions into three main types: universal, selective, and indicated approaches. The literature describing preventive interventions varies markedly in terms of the methodological rigor of evaluation methods. Some studies are simply descriptive or report case illustrations. Others have used quasi-experimental designs, with weak control procedures and/or lack of random assignment to conditions. We also need to bear in mind that selective publishing is likely to occur, with studies that produce positive, significant findings possibly being more likely to reach publication status. Nevertheless, there is convincing evidence within the literature to suggest that some interventions have been effective in preventing, or at least attenuating, the development of child psychopathology.

5.12.6.1 Universal Preventive Interventions

Universal interventions are those that are applied to whole populations. In some instances, universal preventive interventions have been designed to enhance general mental health, whereas others have targeted one specific disorder such as conduct disorders, anxiety, depression, or substance abuse. The majority of universal preventive projects have been applied within school settings. For example, Kellam and Rebok (1992) described two classroom-based interventions that were designed to enhance children's reading skills and prosocial behavior as a means of preventing subsequent conduct and substance abuse problems. Preparatory research had identified reciprocal relationships between children's academic achievement and shy, depressive, and aggressive behavior. The first intervention involved a Mastery Learning curriculum for the enhancement of reading skills. The second intervention was based on the Good Behavior Game that consisted of a team-based, behavior management approach targeted at reducing aggressive behavior. In trials across 19 schools in Baltimore, Kellam, Rebok, Ialongo, and Mayer (1994) reported that the Good Behavior Game had a short-term impact upon aggression, but no direct or indirect impact upon academic achievement. In contrast, the Mastery Learning approach had a direct effect upon enhanced academic achievement, but also produced an indirect reduction in aggressive behavior. The longer term results from first grade intervention upon behavior at sixth grade revealed interesting results. Although there were no overall significant benefits of the Good Behavior Game in comparison to control children, a differential response was found for different groups of children. For males, those who showed the highest rates of aggression in first grade showed the greatest benefit from the Good Behavior Game at sixth grade follow-up. However, the approach was not effective in preventing children who were not aggressive in first grade from subsequently developing problems of aggression. These findings suggest that classroom-based behavior management approaches may offer promise in the prevention of aggressive behavior in children who manifest early disruptive behavior problems.

Reductions in conduct disorder and substance abuse are also goals of the Seattle Social Development Project. This intervention is based on the theoretical premise that strong bonds to family and school serve as protective factors against delinquency and drug abuse. Increases in feelings of attachment, commitment, and beliefs regarding participation in undesirable behavior are considered to be important aspects of the protective process. The project involves a multicomponent, universal preventive intervention that includes teacher training in classroom management and instructional methods, class-based interpersonal problem solving skills, training sessions, and a parent training component (Hawkins et al. 1992). The effects of the program were evaluated in schools within high crime areas. Those children who received the intervention were less likely to have initiated delinquent behavior and alcohol use, and showed higher school achievement four years after participating in the project, in comparison to children from schools or classrooms that did not receive the intervention.

Not all universal preventive studies have focused on conduct disorder as the outcome goal. In some instances the aim has been to prevent the onset of internalizing problems such as depression. For example, Clarke, Hawkins, Murphy, and Sheeber (1993) described two very brief preventive interventions for adolescent depression, neither of which produced significant benefits. Both interventions were conducted with a large number of youngsters within the context of regular classroom education. The first intervention involved three, 50 minute sessions of educational intervention, over three consecutive days, covering the nature of depression, its treatment, the benefits of seeking treatment when needed, and the need to increase pleasant events. No specific behavioral skills were trained. The intervention group was compared with a group of youngsters attending the usual health education class. The intervention had little impact on depressive symptoms for girls, and boys showed a small short-term improvement which was not maintained at 12 week follow-up. In the second intervention, Clarke et al. (1993) altered the program so that it involved five, 50 minute sessions. The first session included a shortened educational component covering the symptoms, causes, and treatments of depression. The remaining four sessions involved a behavioral program to increase participation in pleasant events. No significant benefits were found for either the sample as a whole, or for those adolescents with initial high levels of depression.

The poor results of these programs may make us pessimistic about the value of universal interventions in the prevention of depression among adolescents. However, such a conclusion may be premature. Clarke et al. (1993) criticized their own programs for failing to include a skills training component to rectify those skills deficits (e.g., social skills deficits) associated with depression in young people. In addition, the studies were excessively brief and the follow-up period of 12 weeks was too short to detect long-term benefits. Clarke et al. (1993) proposed that future prevention studies should focus on those factors that have been demonstrated to be risk factors for the development of depression, such as poor social and interpersonal problem-solving skills, overly critical self-evaluation, low rates of self-reinforcement, and pessimistic thinking style.

Drug and alcohol abuse have been the targets of several preventive interventions. Price (1995) provided a valuable outline of the issues facing researchers and practitioners working in this area. Price discussed a variety of approaches to prevent substance abuse, including school-based, family-focused, and media-based programs. The prevention of substance abuse highlights the many different perspectives that can be taken. For example, substance use is influenced by economic factors such as the availability and price of drugs and alcohol. One approach to reducing substance abuse is therefore to manipulate the supply and cost of substances. Of course, this action could also produce negative side effects relating to criminal activities that may act as a means of obtaining money to purchase drugs. Thus, no simple solutions are presented. Although we are still a long way from finding solutions to the prevention of substance abuse in young people, preliminary studies of universal interventions are emerging that provide some encouraging findings relating to the prevention of early stage substance use, such as tobacco smoking (e.g. Caplan et al., 1992; Ellickson & Bell, 1990; Perry et al., 1989).

5.12.6.2 Selective Preventive Interventions

Selective prevention efforts are applied to those individuals who are members of a group, the membership of which places them at increased risk for the development of mental disorders. Over the past 20 years preventive interventions have been applied to a wide range of high-risk groups, focusing on parents and families who are dealing with major life transitions and/or high-risk situations. These include groups characterized by parental psychopathology, premature births, single parents, socioeconomic deprivation, teenage pregnancies, divorce, bereavement of a close family member, exposure to trauma and school transitions.

5.12.6.2.1 Children exposed to socioeconomic deprivation

Several preventive programs have been targeted towards children from high-risk geographical areas with elevated levels of poverty and societal risk factors. In some instances these studies have used random assignment and control groups in order to determine the long-term efficacy of the interventions. For example, Olds, Henderson, Tatelbaum, and Chamberlin (1988) described the Prenatal/Early Infancy Project which aimed to reduce mothers' health-damaging prenatal behaviors (i.e., diet and substance abuse), enhance parenting skills, and provide social support, assistance with continuing education, and contraceptive counseling. Women who received home nurse visitation during pregnancy and until the child was two years old showed significant reductions in preterm births and verified cases of child abuse in comparison to women who did not receive such an active intervention. A home visiting approach was also beneficial in the Early Intervention for Preterm Infants project (Field, Widmayer, Stringer, & Ingatoff, 1980) in enhancing physical and cognitive development among preterm babies born to young, single mothers from low socioeconomic backgrounds. This program focused on teaching mothers about caretaking practices and enhancing parent–infant interactions. Home visiting plus preschool developmental activities have also produced positive results in terms of physical and cognitive development of low birth weight babies (Kraemer & Fendt, 1990).

Some programs have included a wider spectrum of intervention approaches, of which home visiting is just one component. Lally, Mangione, Honig, and Wittner (1988), in a quasi-experimental design, demonstrated that a home visiting approach, in association with child care and early educational enrichment was associated with significant reductions in delinquent behavior at 10 year follow-up. This project involved primarily low-income, single mothers who participated in the intervention from the last trimester of pregnancy through to age five of the child. Home visiting is also an important focus within the recently established Better Beginnings, Better Futures Project in Ontario, Canada, that is aimed at families in socioeconomically disadvantaged areas. This project involves a series of programs, some of which include home visiting as a component. Other aspects of the project include classroom enrichment for teaching of academic and social skills, child care enrichment, parent training, parent support groups, and increasing community resources (Peters & Russell, 1994). The Healthy Start in Hawaii service is also worth mentioning here (US Advisory Board on Child Abuse and Neglect, 1990, cited in Mrazek & Haggerty, 1994). This service was not established as a research study but as a community intervention to reduce child abuse and neglect. The program is designed to identify at-risk children in the first three months of life and aims to screen around 90% of the total population. Following early identification, families are allocated a lay-person home visitor, linkage to a primary health care service, parent education, and child care services. Since the establishment of the Healthy Start program, there has been a gradual decrease in child abuse and neglect cases in Hawaii, although it must be noted that there are no empirical control groups with which to compare the current rates of abuse and neglect of those families who received the intervention.

There are many other programs that have included home visiting as part of their intervention. Other components of multifaceted interventions have included parent education classes, preschool/nursery school facilities to promote social and academic skills, and home-based social and cognitive skills training (e.g., Houston Parent–Child Development Center, Johnson, 1991; Mother–Child Program of Verbal Interaction, Levenstein, 1992). These studies demonstrated that preventive interventions can be effective in enhancing the social and cognitive skills of children from socioeconomically deprived backgrounds. One of the most well-known, preventive projects is the Perry Preschool Program that combined home visiting and intensive preschool education. This selective intervention focused on children and their families who experienced severe poverty and included daily preschool attendance for two years and weekly home visiting by a trained teacher. Long-term follow-ups showed superior academic performance and social adjustment and lower rates of delinquent behavior through to late adolescence, compared to the randomly assigned control group (Berruteta-Clement, Schweinhart, Barnett, Epstein, & Weikart, 1984; Schweinhart, 1987).

Some studies have focused preventive efforts upon school-based interventions, with minimal involvement of parents. For example, Shure and Spivack (1980, 1982, 1988) reported the benefits of an interpersonal problem-solving program that was delivered to small groups of preschool children from economically deprived families. The curriculum ran over approximately three months, and involved several lessons per week to teach problem-solving skills. Children who received the intervention were reported to show enhanced social competence and lower rates of behavior problems in comparison to untrained control children. However, whether preschool interventions of this sort will be beneficial in producing long-term improvements through to adolescence remains to be demonstrated.

In summary, there are now a wide range of evaluative studies demonstrating that preventive interventions can be effective in enhancing social adjustment and decreasing psychopathology (particularly conduct disorder) in children from socioeconomically impoverished backgrounds. However, it is important to note that many of these studies involved relatively small numbers of families and very large numbers of intervention hours. Some studies required a very large investment of time from parents which precluded inclusion of those who were in employment. Furthermore, many studies do not report the cost of the intervention per family. Clearly, the cost of providing weekly home visits for 3–5 years, in addition to daily preschool facilities with low staff–child ratios, is enormous. Thus, although these interventions can clearly produce significant benefits, it remains to be determined whether it is feasible in financial and practical terms to apply such intensive interventions on a large-scale basis. A further problem in existing studies is the relatively high drop-out rate that is often reported, particularly from families with high levels of mobility. Thus, it is important to take into account the drop-out problem in interpreting the results of existing studies, and that efforts are put in place to maximize retention rates in future interventions.

5.12.6.2.2 Assisting children to deal with school transition

Children are required to deal with many changes throughout their lives, but the transition to a new school is suggested to be one of the most stressful (Soussignan, Koch, & Montagner, 1988). Children are required to adapt to different physical, social, and academic environments, with new sets of rules and regulations. Not surprisingly, many children find the transition very difficult and a variety of behavior problems have been linked with school transitions. These include peer relationship difficulties, school refusal, somatic complaints, academic failure, increased substance abuse, delinquency, and school drop-out (Hightower & Braden, 1991).

As a means of preventing adjustment problems associated with transition to secondary school, Felner and Adan (1988) developed the School Transition Environment Project (STEP). The STEP program consists of three components. The first organizes the physical plan of the school into units with home rooms in order to facilitate familiarity with the school environment. Children allocated to the program attend core academic subjects together in these home rooms. This process is suggested to make the school transition less overwhelming and stressful to incoming students. The second aspect of STEP includes a "home room" staff member who has the responsibility for taking the daily attendance list, following up non-attendances, and counseling of pupils regarding academic or school adjustment problems. The final component involves a coordinated liaison between teaching and school counseling staff. The overall aims of the program are to increase personal relationships between pupils and staff and to create subenvironments within the overall large school environment.

Evaluations of the STEP approach have demonstrated that children who participated in the program showed greater improvements in academic performance and self-esteem, better school attendance, and lower school drop-out rates compared to control children who did not take part (Felner & Adan, 1988). Furthermore, the benefits have been replicated in a variety of different school settings with children from various social backgrounds. Overall, the approach appears to be a valuable method of reducing problems associated with school transition and provides a model which could be routinely adopted by school authorities.

5.12.6.2.3 Children of parents with psychiatric disorders

Given the convincing evidence that parental psychopathology is a risk factor for the development of psychological problems among children and adolescents, it is not surprising that researchers and practitioners are beginning to examine the value of applying preventive interventions with children of mentally ill parents. To date, however, there are few controlled evaluations to determine the effectiveness of such efforts. There is a strong theoretical case to suggest that preventive efforts should be directed towards the children of parents who experience chronic problems of depression, anxiety or psychosis. In particular, it is important that these parents are taught to use positive parenting skills and that support mechanisms are put in place to increase the chance that parents will continue to use these skills during episodes of psychological problems. However, we must also acknowledge that the children who live with a mentally ill parent may also need to learn coping and survival skills to assist them in dealing with traumatic life circumstances and phases of poor parenting. In one of the few experimental evaluations of a prevention program with children of severely depressed parents, Beardslee, Salt, Porterfield, and Rothberg (1993) reported positive results for two approaches. The first intervention involved a clinician-led psychoeducational method, whereas the second approach was lecture-based. However, as the study did not include a no-intervention comparison group, it is difficult to draw firm conclusions about the benefits of the interventions. Clearly, there is an urgent need for methodologically rigorous examinations of preventive efforts with children of mentally ill parents.

5.12.6.2.4 Children who have experienced trauma

Some aversive events occur unexpectedly and are of sufficient magnitude that they constitute a traumatic experience to children. Such traumas include environmental disasters (e.g., earthquakes, war, storms, or fires), serious accidents, and death of a close family member. Family break-up through parental separations and divorce could also be regarded as a traumatic event, although this area is covered separately below. There is now considerable evidence that children who experience traumatic events are at increased risk of developing emotional and behavioral problems. For example, following trauma, children show increased levels of fears relating to stimuli associated with the traumatic event, avoidance behaviors, somatic complaints, depression, sleep disturbance, and intrusive thoughts and images (Dollinger, 1986; Dollinger, O'Donnell, & Staley, 1984; Terr, 1981; Yule & Williams, 1990). Although such problems ameliorate relatively quickly for most children, a significant proportion of children show persistent anxiety symptoms for many months after the trauma (Terr, 1981). There is therefore a strong case for rapid intervention following trauma in order to prevent the development of persistent psychological problems.

Although much has been written about the need for interventions to prevent long-term psychological difficulties following trauma in children, we still have very little empirical evidence to permit us to determine the most effective approaches to prevention. Sugar (1989) emphasized the need for initial interventions with the parents of children who experience a traumatic event, given the evidence that parent reaction plays a highly significant role in determining child response (McFarlane, 1987). In large-scale disasters which affect whole communities, Sugar (1989) also stressed the need for community counseling and crisis-oriented group approaches in order to provide mutual support, decrease isolation and provide a larger perspective for the individual. Sugar pointed out, however, that the cornerstone of therapy should be individual counseling with children, which takes into account their developmental level and specific details of the traumatic situation experienced. The approach taken to intervention should therefore be tailored to the needs of each child.

A variety of approaches have been used in what is commonly termed the "debriefing" of trauma victims. Yule (1991) suggested that this procedure should commence somewhere between 7 and 14 days following the event, with most survivors being too numb to benefit from counseling prior to this time. Nevertheless, Yule acknowledged that there is a lack of data to validate this proposal and we really do not know what type of intervention should best be used nor at what time after the occurrence of a traumatic event. Yule (1991) proposed a theory-driven approach to trauma counseling with children, based on Rachman's (1980) model of emotional processing which emphasized the need for vivid and prolonged exposure to disaster-related cues in order to facilitate emotional processing. Children may be trained in relaxation skills and gradually exposed to stimuli and memories relating to the trauma event. They are encouraged to describe their reactions and given reassurance that such reactions are understood and are a normal response to an abnormal experience.

To date, there is a lack of controlled experimental evaluations to enable us to identify the most effective means of preventing child psychopathology following trauma. There are many case studies and descriptive reports in the literature, but we now need carefully designed experimental evaluations.

5.12.6.2.5 Children whose parents separate or divorce

Parental divorce has been suggested to represent one of the most common and severe life stressors that confront children and adolescents (Hightower & Braden, 1991; Hodges, 1991). For some children, the emotional consequences may include depression, anger, disruptive behavior, anxiety and/or withdrawal, particularly in the first two years following the divorce or separation (Hess & Camara, 1979). Fortunately, evidence suggests that many children adapt well following family break-ups (Amata & Keith, 1991; Forehand, 1992). To a large extent, the adverse emotional consequences of parental separation and divorce are influenced by the quality of the relationships of the family members involved (Hess & Camara, 1979). Hess and Camara (1979), for example, reported that the negative effects of divorce were considerably less when positive relationships between the parents were maintained. Positive relationships between the child and both the custodial and the noncustodial parents were also found to be important in protecting the child from the negative effects of divorce. This study highlighted the importance of government and social service policies that facilitate positive relationships between ex-partners following separation and divorce. Mediation may be beneficial in reducing disputes between parents regarding custody, access, and property settlements.

We need to be able to identify those children who are most at risk of developing adverse reactions to parental divorce and separation and target preventative programs in their direction. Several programs have been developed for use with children whose parents have recently divorced (e.g., Hodges, 1991; Pedro-Carroll & Cowen, 1985). Pedro-Carroll and Cowen outlined the Children of Divorce Intervention Project (CODIP) which was developed for use on a small group basis within schools. The project aimed to prevent or ameliorate academic, behavioral, and emotional problems that children often experience during or after their parents' divorce. Components of the program included: (i) development of a supportive group environment; (ii) facilitation of the identification and expression of divorce related feelings; (iii) promotion of understanding of divorce-related concepts and rectifying misconceptions; (iv) teaching of coping skills, including social problem-solving skills; and (v) enhancement of children's positive perceptions of themselves and their families. The program involved 12–16 sessions, with methods including discussion, role-play, skills training, and home-based tasks.

Evaluations of the program demonstrated its effectiveness in producing reductions in anxiety, fewer behavioral problems, greater gains in school competencies, decreased feelings of self-blame, and better ability to solve divorce-related problems in comparison to children of divorce who did not participate in the project. Follow-up information suggested that the benefits were maintained for the majority of children at two years follow-up, although only around half the children continued to show the gains they had made over the comparison group at three year follow-up. Although independent replications using this approach are required, the CODIP program appears to offer promise in the prevention of adverse psychological consequences in children following parental divorce.

5.12.6.2.6 Children who show multiple risk factors

In view of the convincing evidence that risk factors have a multiplicative effect, not just an additive one, there is a strong case for focusing preventive efforts on young people who show a combination of risk factors. For example, Dishion and Andrews (1995) reported a study designed to prevent conduct disorder and substance abuse among "high-risk" adolescents who showed at least four risk factors. These risk factors concerned a range of factors such as poor parent–child relationships, lack of school engagement, problem behavior, early substance use, family substance use, and stressful life events. A parent management program involving 12, 90 minute, weekly sessions was beneficial in reducing family conflict and behavioral problems at school in comparison to the no-intervention group. There was also a trend towards longer-term reduction in substance use for the parent management group. Interestingly, the two comparison interventions that included grouping of high-risk youths together in sessions actually showed evidence of negative influence upon school behavior problems and substance use. This problem is discussed further below.

5.12.6.3 Indicated Preventive Interventions

As defined above, indicated prevention approaches are those that are applied to individuals who, on examination, are found to manifest a risk factor, condition, or abnormality that identifies them as being at high risk for the future development of psychopathology. The main distinction between selective and indicated prevention refers to the degree to which the risk factor is intrinsic to the individual rather than the group. Thus, selective interventions target persons who are judged to be at risk as the result of being a member of some group, the membership of which is known to be a risk factor for the development of psychopathology. In contrast, indicated prevention targets persons who possess some characteristic intrinsic to the individual that places them at risk for the development of psychopathology. Given our knowledge of early, mild symptomatology as a risk factor for later clinically significant psychopathology, programs that target mild psychopathology (alternatively known as early intervention) will be regarded as a form of indicated prevention. These approaches aim to identify early symptoms of emotional and behavioral disorders through screening programs, usually during early childhood. Such programs aim to break the trajectory typically involved in the development of many forms of psychopathology, including conduct disorder, depression, anxiety, and psychotic episodes.

5.12.6.3.1 Early intervention to prevent conduct disorder

Several programs have been developed for early identification with children who show subclinical levels of conduct disorder and aggression. A variety of approaches have been used in attempts to break the progression from early disruptive behavior problems to a full-blown conduct disorder. These have included parent training approaches, child-focused interventions, and multicomponent programs that involve a variety of parent- and child-focused methods. The rationale behind these interventions is the proposition that poor parenting skills, academic failure, and poor social skills are risk factors for the development of conduct disorder. Thus preventive interventions have focused on enhancing factors such as parenting, social, and academic skills.

For example, Tremblay et al. (1991, 1992, 1995) examined the outcome of a program designed to prevent serious conduct problems among a group of disruptive kindergarten boys from inner-city, low socioeconomic neighborhood schools. One hundred and seventy two boys, who were identified at the end of preschool as showing high levels of disruptive behavior, were randomly assigned to a preventive intervention, observational control, or no contact. The preventive intervention was conducted over a two-year period and involved parent and child interventions. The parent component involved up to 46 individualized home-based training sessions, with a mean number of 17.4 sessions focusing on monitoring of children's behavior, use of behavioral parenting methods, and crisis management techniques. The child-focused component included small group prosocial skills training, problem-solving, and self-control methods. These sessions were conducted over two school years, and included a small number of prosocial peers within each group.

Up to age 12, the boys who had earlier received the intervention showed better school attendance, were rated by their teachers as less disruptive in the classroom, and were less likely to have required special education experiences (Tremblay et al., 1992). However, the longer-term results reported by Tremblay et al. (1995) are extremely interesting. By age 15, the difference between preventive intervention and control boys had disappeared in terms of school placements and behavior in the classroom. Generally, there was a trend for behavior problems to decline with age for boys, irrespective of whether they participated in the preventive program. Juvenile court records also showed no significant differences between the intervention and control groups in terms of official court sanctions between ages 12 and 15. Furthermore, there were no differences between groups in terms of the boys' perceptions of their parents' punishment behavior, although the boys in the preventive group perceived their parents as engaging in a higher level of supervision than did the control group. Thus, despite a costly intervention over a two-year period, the long-term results of this study were disappointing. Positive benefits were noted in terms of classroom behavior and academic performance throughout elementary school, but the impact had largely disappeared by age 15. Tremblay et al. (1995) proposed that future studies should include booster sessions for boys and parents in order to maintain the benefits that are evident during elementary school years. They suggested that booster units are needed that focus on problem-solving skills, life skills, study skills, conflict resolution, self-control, and academic skills during early adolescence.

The value of the Tremblay et al. (1995) results is that they highlight the importance of extensive long-term follow-up. It will be several years before many of the recently established early intervention studies for the prevention of conduct disorders obtain adequate follow-up data to permit valid conclusions to be drawn about their long-term efficacy. For example, the FAST Track Project (Conduct Problems Research Group, 1992) is being conducted in multiple sites across the USA. Participants are preschoolers and their families where the youngsters have been identified as showing high levels of noncompliance and aggression at age four and therefore are considered to be at risk for future development of conduct disorders. The intervention continues over several years, with components focusing on the training of social skills, increasing peer acceptance, remedial educational tuition, and parent training. Parents are paid a small amount to attend the sessions and transport and child care is provided for the sessions. The long-term effectiveness of this approach is yet to be determined.

Lochman, Coie, Underwood, and Terry (1993) reported a controlled evaluation of a program targeted at fourth grade children who were identified as socially rejected and aggressive at school. The intervention included social skills training, anger management, and cognitively-based components to teach interpersonal problem solving and appropriate perception and interpretation of interpersonal cues. The school-based curriculum included small group and individual sessions over 12–18 sessions. By one year follow-up, there was a problem of drop out which restricts the conclusions that can be drawn. However, of those children who were both aggressive and rejected and who remained in the study at one year follow-up, those who received the intervention were rated by their teachers as being significantly less aggressive than those in the randomly assigned control condition. Whether these benefits are maintained at 5–10 year follow-ups remains to be demonstrated.

An alternative approach to early intervention with children who show disruptive and aggressive behavior during preschool years is the Triple P (Positive Parenting of Preschoolers) program described by Sanders and Markie-Dadds (1996). This project involves a multilevel approach in which the intensity of the intervention is tailored to the severity of the presenting problems of the child and family. Level 1 involves a community-based self-help approach involving tip sheets for parents and a manualized program concerning parenting skills for commonly occurring behavior problems. The Level 2 intervention includes minimal contact with a therapist by telephone in addition to the written self-help materials. Active training in parenting skills is then included at Levels 3 and 4, being applied to those families for whom the child behavior problems are not complicated by additional family problems such as marital discord or parental depression. In Level 5, intensive behavioral parent training is enhanced with treatments to reduce parental depression and marital discord. Short-term results suggest that this approach appears to offer promise in reducing subsequent conduct problems. However, it is not yet clear how effective the multilevel intervention strategy will be in producing long-term benefits through to adolescence, nor when applied on a large-scale, community basis.

5.12.6.3.2 Early intervention to prevent anxiety and depression

Recently, researchers have started to examine the benefits of preventive interventions with children who show mild depressive symptoms, again trying to break the trajectory in the development of clinical depression in later adolescence. Clarke et al. (1995) reported the results of a preventive program with high school adolescents who were assessed as showing elevated depressive symptomatology. These youngsters were randomly assigned to a 15-session cognitive group intervention or a "usual care" control condition. Survival analyses indicated a significant 12-month advantage for the prevention program, with affective disorder total incidence rates of 14.5% for the active intervention and 25.7% for the control condition. Jaycox, Reivich, Gillham, and Seligman (1994) also reported positive findings in the prevention of depression of primary school children who reported mild symptoms of depression and parental conflict in the home. The intervention program involved teaching children to shift their cognitive style to more optimistic, rather than pessimistic, interpretations and training in interpersonal skills. At six-month follow-up, the preventive intervention group reported fewer symptoms of depression compared to a nonintervention control group, an effect that was still evident at two-year follow-up (Gillham, Reivich, Jaycox, & Seligman, 1995).

An early identification and intervention approach is also being trialed in the prevention of anxiety disorders in children and adolescents. Dadds, Spence, Holland, Barrett, and Laurens (1997) described an intervention for children who were identified as being at risk for the development of anxiety disorders by virtue of showing mild levels of anxiety and fearfulness. The aim of the project is to reduce symptoms of anxiety and enhance protective factors, such as child coping skills and appropriate parenting skills, in order to reduce the later development of anxiety disorders. After recruitment and diagnostic interviews with 1786 7–14 year olds, 128 children were selected and assigned to a 10-week school-based child and parent-focused psychosocial intervention, or a monitoring group.

At postintervention, approximately 10% of children in both groups had developed a full *DSM-IV* anxiety diagnosis, with no significant differences between groups. However, at six months follow-up, 54% of the children in the monitoring group had developed an anxiety disorder, compared with 16% in the intervention group (Dadds et al., 1997). The finding that over half of the children in the monitoring group who were "at risk" only, progressed into a formal anxiety disorder at the six month monitoring period, highlights the importance of late childhood and early adolescence as a critical time in the development of anxiety disorders (Spence & Dadds, 1996). The long-term benefits of this preventive intervention are still being examined.

To date, research into the prevention of anxiety and depressive disorders in children who manifest early symptomatology in these areas is only in an embryonic state. However, the results so far are encouraging and justify continued investigation of methods to interrupt the trajectory from preclinical symptomatology to clinical depression and anxiety.

5.12.6.3.3 *Early intervention to prevent psychotic episodes*

One of the most exciting developments in the area of indicated prevention concerns early intervention with individuals who show early signs of psychosis. For example, the Early Psychosis Prevention and Intervention Centre (Jackson, McGorry, Edwards, & Hulbert, 1996) provides early intervention for 16–30 year olds with an emerging psychosis. A cognitively-oriented psychotherapy approach is taken in the multiphase program. Intervention methods include development of a sense of hope, identifying personal strengths, developing coping mechanisms, education about psychosis, and establishment of social support networks. Preliminary results suggest that participants with first episode psychosis show lower negative symptoms and reduced disability scores compared to those who refused to participate or dropped out of the program. Although the lack of random assignment to groups represents a methodological limitation, the preliminary results suggest that early detection and intervention programs for psychosis warrant further empirical examination. The program is also limited to individuals who have already experienced their first episode of psychosis. Some interesting research reported by Birchwood (1995) suggested that prodromal signs (such as loss of mental agility, racing thoughts, disjointed thinking and confusion, feelings of derealization and heightened perception) can reliably predict the imminent onset of new episodes of psychosis. Birchwood used case studies to illustrate how cognitive–behavioral interventions and/or medication can be used to prevent subsequent episodes of psychosis in young people who manifest these prodromal signs. The programs described by Birchwood (1995) and Jackson et al. (1996) involved individuals who have already manifested their first episode of psychosis. Monitoring and identification of prodromal signs is used to cue the use of techniques to prevent the onset of subsequent episodes of psychosis. However, there is also some tentative evidence that it may be possible to prevent first episode by early detection of presymptoms of psychosis and intervention with adolescents and young adults (e.g. Falloon, 1992).

5.12.7 DIFFICULTIES AND CHALLENGES

There are an enormous number of practical difficulties in implementing preventive interventions and in evaluating their efficacy. The following section attempts to outline just a few of these issues for consideration. For example, it is important to bear in mind the possibility that preventive efforts may, in some instances, be counterproductive. We need to consider the possible detrimental effects of labeling individuals as being "at risk" of developing psychopathology. Any preventive efforts must ensure that the intervention does not produce changes in the behavior of significant others, such as peers, teachers, or family members that further increases the chance that the young person will develop emotional or behavioral difficulties. Similarly, preventive efforts must be cautious about the potential negative side effects of bringing together children who share common risk patterns. This is particularly relevant to programs that bring together adolescents who share risk factors relating to the development of substance abuse or severe conduct disorder. In some instances, the aggregation of high-risk youths has produced an iatrogenic effect. For example, Dishion and Andrews (1995) found that interventions that aggregated high-risk youths into groups produced escalations in tobacco use and problem behavior at school. This effect was not evident in the intervention that focused on parenting skills training and did not include group attendance by the adolescents.

A second issue for preventive interventions is to whom should preventive efforts be targeted in order to produce the most cost-effective benefits. One of the most significant areas of research for the future will be identification of combinations of risk factors that accurately predict the development of psychopathology and for which there are effective methods of change. This will enable us to target preventive efforts more specifically to those at greatest risk. Lochman et al. (1995) proposed that the most useful risk markers for a prevention program are those that are potentially modifiable as a result of intervention, or those that are markers for other changeable processes that mediate negative outcome Lochman et al. (1995) described how a multiple gating procedure can be used to identify children at risk of developing conduct problems. This study showed how parent ratings of early childhood behavior made a significant contribution over and above teacher ratings of child behavior in the prediction of subsequent conduct problems at school. Studies of this type will be valuable in steering future directions for prevention research and policy.

Although it may make sense to suggest that limited funds for prevention should be spent on those children most at risk rather than upon universal interventions, we do not have the evidence to back up this assumption. We need to determine whether universal interventions applied to whole populations can produce sufficiently strong results to impact upon the development of psychopathology among children with multiple risk factors. Given the relatively disappointing long-term effects of those intensive interventions that have been focused upon the prevention of behavior problems among children with mild symptomatology (e.g., Tremblay et al., 1995), it seems unlikely that a universal intervention could produce significant long-term benefits for these children. Nevertheless, this possibility warrants examination. An alternative approach is to follow the multilevel example outlined by Sanders and Markie-Dadds (1996). This system requires an assessment and prevention strategy that provides relatively cheap community-based initiatives that are likely to be helpful to the majority of families. More intensive approaches are reserved for those families and children who show persistent behavior problems or multiple risk factors. These multilevel preventive strategies require that systems are in place to identify those families who are in need of more complex interventions than those available at a community, universal level.

A third area of concern is the need to provide cost–benefit analyses, in terms of the cost of the preventive intervention vs. the reduction in costs of treatment of psychopathology. If mental health policymakers and planners are to be convinced that there is a case for investing large amounts of funding in preventive efforts, they need to be shown evidence of the likely economic benefits to the community. In the area of physical health it is easier to provide estimates regarding the cost savings of prevention programs. For example, it has been estimated that the cost–benefit ratio of the mumps–measles–rubella vaccine program in the USA is 14:1. For example, the 1983 immunization scheme produced cost savings of US$1.4 billion (White, Koplan, & Orenstein, 1985). The benefits of prevention in mental health are much harder to estimate. However, it should be possible to determine the cost of preventive interventions compared to the cost of long-term treatment of full-blown clinical cases through indicators such as the cost of mental health consultations, time off work, hospitalization, and pension payments.

5.12.8 CONCLUSIONS

Considerable advances have been made over the past 20 years in the area of prevention of child and adolescent psychopathology. The evidence presented in the present chapter suggests that we have made considerable progress in identifying risk and protective factors relating to the development of child and adolescent psychopathology. It is now feasible to identify major risk and protective factors for the development of conduct disorders and internalizing problems in young people and many of these are potentially modifiable through psychological interventions. There have now been many studies of universal, selective, and indicated preventive interventions that have reported positive effects in reducing the risk for development of emotional and behavioral problems. However, most of the published papers relating to the efficacy of prevention of psychopathology are limited by relatively short follow-up periods or have failed to include a valid comparison group against which to compare changes over time. It is important therefore to bear these limitations in mind when interpreting the literature. There are still many unanswered questions. A great deal more research is needed before we can draw firm conclusions about which psychological problems can be prevented, what methods are most effective in preventing specific mental health problems, to whom should preventive programs be directed, and whether prevention is best directed at whole populations, or those with specific risk factors. Many methodologically rigorous and theoretically sound preventive studies are currently underway and the next decade should provide answers to many of these questions.

5.13.1 INTRODUCTION

Since Freud's description of separation fears in Little Hans at the turn of the century, anxiety disorders in children have received scarce but increasing attention from clinical researchers. Only recently, however, have controlled studies into the epidemiology, development, and treatment of these children gathered momentum. There are a number of reasons for this neglect. Across most classes of psychopathology, children receive less attention than adults (Kazdin, 1985), and children with anxiety disorders often do not attract the attention of mental health services because their behavior may be relatively cooperative and unobtrusive compared with disruptive peers. Despite this, there is evidence to suggest that some forms of childhood anxiety are severely debilitating and predictive of chronic mental health problems.

Through this century, a number of critical issues regarding anxiety in children have emerged. Because far more research has been conducted into anxiety in adults, there has been a tendency for child researchers to borrow conceptual models and treatment techniques from the adult literature. The value of this has been assumed rather than supported by hard data and thus the field is becoming increasingly careful to incorporate and evaluate developmental factors into its borrowed models. Other issues are common to most forms of child psychopathology. The reliability, validity, and clinical utility of diagnostic systems remain controversial issues despite much effort to refine the various categorical systems currently in use. While this is true for all forms of psychopathology, the use of formal diagnoses with children has many unique problems raised by the rapid changes children go through and the diversity of stakeholders such as the child, parents, and teachers that are involved in the child's well-being. Further, the childhood anxiety disorders continue to elude attempts to find discrete categories, with overlap and comorbidity being the rule rather than the exception.

The relative importance and interaction of temperamental vs. learned factors has moved beyond simplistic nature–nuture debates to models that emphasize multiple causal variables that interact in predictable development sequences. Thus, a disorder is seen as taking a developmental trajectory through predictable changes and stable phases. For conduct disorder in children, much progress has been made in mapping common trajectories; for anxiety disorders, relatively little is known. Thus, the links between child and adult anxiety remain an area of speculation. The twentieth century has also heralded the growth of behavioral and cognitive sciences and family therapies as major clinical and scientific movements. Both are important to anxiety in children. Contemporary conceptual and treatment models emphasize the interactions of learning factors, cognitive style, and family process. Recently, exciting and important work has shown that these can be studied under controlled conditions and used with great effect to bring about clinically significant improvements in anxious children.

The aim of this chapter is to review current knowledge of the nature, development, and treatment of the major classes of childhood anxiety. Specifically, it will focus on the more general forms of anxiety disorder such as separation anxiety, social fears, and generalized anxiety states. Simple phobias, obsessive compulsive disorder, and traumatic stress disorder are covered elsewhere in this volume.

5.13.2 ANXIETY DISORDERS

5.13.2.1 Phenomenology

Marks (1969) described fear as "a normal response to active or imagined threat in higher animals ... (comprising) an outer behavioral expression, an inner feeling, and accompanying physiological changes" (p. 1). Anxiety, a closely related construct, has been defined as "a dysphoric, aversive feeling similar to fear that arises without an obvious external threat" (Miller, 1983, p. 338) and "apprehension, tension, or uneasiness related to the expectation of danger, whether internal or external" (Kendall et al., 1992, p. 1). Although distinctions are typically made between the two constructs, the prevailing diagnostic classification system, the *Diagnostic and statistical manual of mental disorders* (*DSM*) (American Psychiatric Association [APA], 1994), conceptualizes both fear and anxiety as being manifested in very similar physiological, cognitive, and affective patterns (Kashani, Dandoy, & Orvaschel, 1991). Based on Lang's (1968) tripartite model, anxiety is typically viewed as a multidimensional construct involving physiological, behavioral, and cognitive components or symptoms.

Fear and anxiety are common, typically transitory, and, in many situations, adaptive in that they protect the individual from harm. This being the case, anxiety and anxiety disorders are typically conceptualized as varying quantitatively along a continuum, with the degree of distress, impairment in functioning, and/or interference with daily life, discriminating between what is "normal" and adaptive and what is problematic. The difficulty, of course, comes in deciding where normal anxiety ends, and clinical anxiety begins. This difficulty is especially marked in work with children owing to developmental considerations that must be taken into account. Given that the rate of development is far greater during childhood and adolescence than at any time in life, knowledge of what are "normal" fears and anxieties at each developmental stage is vital when attempting to ascertain whether or not a child suffers from clinical anxiety. A fear that is normative for a preschool-aged child may be maladaptive if experienced by an adolescent.

As a consequence of children's developmental experiences and increasing cognitive abilities, the content of their fears and anxieties changes over time, with the focus generally moving with age from concrete, external fears to increasingly internalized and abstract anxieties. Thus, infants tend to fear strangers, loud noises, and strange and unexpected objects (Jersild & Holmes, 1935), while children of one and two years of age fear separation from their parents, loud noises, animals, the dark, and the toilet (Miller, Barrett, & Hampe, 1974). Of these, fears about animals, the dark, and separation from parents frequently persist into a child's fifth year. Between the ages of four and six, predominant fears focus on kidnappers and robbers and supernatural beings, such as ghosts and monsters. At the age of approximately six years, fears of bodily injury, death, and achievement develop (Bauer, 1976; Croake & Knox, 1973), and for many children, these continue into early adolescence. The final developmental stage appears to begin at approximately 10 or 11 years of age, when fears regarding social comparison, physical appearance, personal conduct, and school examinations predominate (Croake, 1969; Miller, Barrett, Hampe, & Noble, 1972). Factor analyses have provided additional information regarding the organization of the content of childhood fears, with the most commonly accepted solution yielding five factors consisting of fear of: failure and criticism, the unknown, injury and small animals, danger and death, and medical procedures (Ollendick, Matson, & Helsel, 1985).

McFarlane, Allen, and Honzik (1954), for instance, reported that 90% of the normal children aged two to 14 years in their sample reported at least one specific fear. The vast majority of children report experiencing multiple fears, and although the number of self-reported fears appears to decline with age, this reduction does not seem to be as great as might be expected. Thus, Ollendick et al. (1985) reported an average of 14.2 fears in children aged seven to nine years and an average of 11.6 fears in their sample of 16 to 18-year-olds. Another consistent finding is that girls typically report more fears than boys (although whether this is due to actual gender differences or sociocultural factors remains unclear). King et al. (1989) reported the average numbers of fears for males and females aged between eight and 16 years to be 10 and 18, respectively. Across cultures, total scores on the Revised Fear Survey Schedule for Children (Ollendick, 1983) appear to be similar for children and adolescents in English-speaking countries (Ollendick, King, & Frary, 1989; Yule, Udwin, & Murdoch, 1990), although Dutch children have been found to score comparatively lower (Oosterlaan, Prins, & Sergeant, 1992) and Portuguese children to score comparatively higher (Fonseca, 1993) than their American, Australian, and English counterparts. The most common fears reported by children and adolescents, however, appear to be stable across different countries and cultures.

In summary, fears and anxieties are common in children and adolescents and in the majority of cases, they are age-appropriate, mild, frequently adaptive, and transitory. Unfortunately, for some children the reverse is the case. The fear and anxiety they experience is so severe and/or pervasive that it can cause intense distress, functional impairment, and interference. It is upon this group that the remainder of this chapter will focus.

5.13.2.2 Diagnostic Features/Differential Diagnosis

The revised third edition of the *DSM* (*DSM-III-R*) (APA, 1987) listed three anxiety disorders that typically begin in childhood or adolescence. These were:

(i) Separation anxiety disorder, defined as undue anxiety regarding separation from significant figures in the child's life. The child's reaction to such separations is beyond that expected for his or her developmental level, and may at times approach the level of panic (Gittelman-Klein, 1988).

(ii) Avoidant disorder, defined, as extreme withdrawal from and/or avoidance of, contact with unfamiliar people. In order to meet diagnostic criteria for avoidant disorder, a child must manifest anxiety regarding new people and situations that is sufficiently severe to interfere with social functioning, while at the same time demonstrating a desire and a capacity for warm and close relationships with familiar people (such as family members).

(iii) Overanxious disorder, defined as exaggerated or undue anxiety or worry. This diagnostic category is characterized by generalized anxiety that may include: self-consciousness; excessive worry about future events (e.g., going to see a doctor), or about past events (e.g., something the child said that may have been taken the wrong way); and anxiety about performance and competence.

In addition to these three anxiety disorders of childhood and adolescence, children could also be diagnosed with anxiety disorders of "adulthood." These included agoraphobia, panic disorder with or without agoraphobia, specific or simple phobia, social phobia, obsessive compulsive disorder, post-traumatic stress disorder, acute stress disorder, generalized anxiety disorder, anxiety disorder due to a general medical condition, substance-induced anxiety disorder, and anxiety disorder not otherwise specified.

With the introduction of the *DSM-IV* (APA, 1994), categories have been changed so that only one anxiety disorder of childhood or adolescence remains—separation anxiety disorder. Avoidant disorder and overanxious disorder have been effectively subsumed into the diagnoses of social phobia and generalized anxiety disorder respectively. In addition, a child may still be diagnosed as suffering from any of the anxiety disorders of adulthood.

As it pertains to childhood anxiety, the classification system used in the *10th edition of the international classification of disorders* (*ICD-10*) (World Health Organization, 1992) is very similar to that used in *DSM-IV*. The differences between the *DSM-IV* and the *ICD-10* adult anxiety categories are minor and insignificant. For the childhood disorders, as is the case in *DSM-IV*, all anxiety diagnoses are grouped together in a single category, which is then split into a number of subcategories. In *ICD-10* these include: separation anxiety disorder; phobic anxiety disorder; social anxiety disorder of childhood; sibling rivalry disorder; and other childhood emotional disorders (including identity disorder and overanxious disorder).

It is important to note that very little empirical research has been conducted to validate the diagnostic categories for child anxiety disorders (Silverman, 1992; Werry, 1994). Although successive versions of the *DSM* have placed increasing emphasis on empirical research, Werry contended that, as yet, the major field trials aimed at validating the childhood anxiety disorders have not been undertaken. However, as Spence (1996) notes, the little evidence that has been available has typically been utilized effectively in developing the *DSM* system. For example, the diagnostic category of avoidant disorder was omitted from *DSM-IV* after research indicated that it did not differ sufficiently from the category of social phobia to justify its inclusion (Francis, Last, & Strauss, 1992). In a similar way, overanxious disorder was subsumed by generalized anxiety disorder on the basis of empirical research (Beidel, 1991).

The controversy over whether the childhood anxiety disorders are indeed distinct clinical entities is further fueled by the overlap in diagnostic criteria across the disorders (for instance, fears of poor performance and negative evaluation are common among children with both social phobia and generalized anxiety disorder), and by the consistent failure of research to differentiate between the different childhood anxiety disorders in terms of etiology. Further, comorbidity among the childhood anxiety disorders is common, much as it is for adults (Sanderson, Di Nardo, Rapee, & Barlow, 1990). Klein and Last (1989) report that almost all anxiety disorder children meet criteria for at least one other anxiety disorder, most commonly overanxious disorder. Similarly, over 50% of children diagnosed with overanxious disorder report comorbid anxiety disorders.

Depression is also commonly reported as a concomitant condition in the childhood anxiety disorders (Brady & Kendall, 1992). The precise figures have varied somewhat, with two small studies reporting either no anxious children meeting criteria for depression (Hershberg, Carlson, Cantwell, & Strober, 1982) or over 80% meeting criteria (Bernstein & Garfinkel, 1986). These discrepancies may be due to a confound with age since older children with overanxious disorder or social anxiety disorder have been found to be more likely to meet criteria for comorbid depression than younger children (Last, Hersen, Kazdin, Finkelstein, & Strauss, 1989; Strauss, Lease, Last, & Francis, 1988). Last et al. (1987) reported that approximately 33% of their population of overanxious disorder and social anxiety disorder children also met criteria for major depression, a figure more in line with the adult literature (Sanderson et al., 1990).

Recently, research has been conducted that provides some support for the *DSM* classification of anxiety disorders. Spence (1996) employed confirmatory factor analysis to test whether the pattern of anxiety symptoms among a community sample of children is in keeping with the *DSM-IV* classification. Using two samples of 698 children aged between eight and 12 years, a model comprising six discrete but correlated factors (reflecting the areas of panic/agoraphobia, social phobia, separation anxiety, obsessive-compulsive problems, generalized anxiety, and physical fears) provided an impressive fit of the data, while the high correlations among latent factors were more than adequately explained by a higher-order model in which each of the six first-order factors loaded on a single, second-order factor (Spence, 1996). Thus, Spence concluded that the *DSM-IV* diagnostic categories of anxiety disorders in children have validity in terms of a strong second-order factor related to anxiety in general, within which the specific categories of anxiety can be identified.

A number of studies have assessed inter-diagnostician reliability with childhood anxiety disorders. Two issues related to reliability are important. First, there is the issue of the degree of agreement between two interviewers who have information from the same source. Second, given that children rarely go for treatment without the urging of a guardian, there is the issue of the degree of agreement between two different sources of information, most commonly, parent and child.

Looking first at the issue of agreement between two interviewers, a number of studies have been conducted showing somewhat mixed results, with kappas ranging from 0.22 to 1.00 (see Silverman, 1991, for a review). Many of these differences are likely to be a result of methodological issues so that data are currently inconclusive with respect to the reliability of childhood anxiety disorders (Silverman, 1991). Nevertheless, some suggestions can possibly be made. First, it seems that the use of structured clinical interviews can greatly enhance reliability (Last, 1988). Second, reliability appears to be considerably better when the second rating is based on a recording of the first, rather than having two clinicians separately interviewing the same source (Silverman, 1991). This latter finding suggests that while the criteria for childhood anxiety diagnoses may be quite reliable, the informants are not.

Rapee, Barrett, Dadds, and Evans (1994) compared inter-rater reliability using the Anxiety Disorders Interview for Children (ADIS), parent and child versions (Silverman & Nelles, 1988), to assess the diagnostic status of 161 children referred to an anxiety disorders clinic. It should be noted that Rapee et al. (1994) reported difficulties in differentiating social phobia from avoidant disorder and so these were grouped together as social phobia. First, interviewers were provided with either live or videotaped information from both parents and the child, yielding kappa coefficients of 0.63–0.82 across the different anxiety disorders. Similar agreement levels were found based on either parent interviews or child interviews alone. However, the agreement levels calculated by comparing diagnoses based on parent interviews with diagnoses based on child interviews were low, especially for overanxious disorder which was much more frequently reported by parents than children. Overall, the results indicate that the use of a structured interview can produce moderately to highly reliable diagnoses using the *DSM-III-R* system for childhood anxiety disorders, and that utilizing different sources of information is important in reaching an accurate final consensus diagnosis. Other research investigating the agreement between different sources has indicated that information derived about the child from the parents is often quite different from that reported by the child (see Klein, 1991, for a review) and different again from teachers' reports (Stavrakaki, Vargo, Roberts, & Boodoosingh, 1987). At present there is no evidence to indicate that one source of evidence is any more valid than another, thus the recommendation is that multiple informants are used in the diagnosis of childhood disorders.

5.13.2.3 Prevalence

The results of recently conducted epidemiological studies indicate that anxiety disorders are probably the most common category of childhood and adolescent disorders (Bernstein & Borchardt, 1991). In a large epidemiological study employing a semistructured diagnostic interview schedule, Kashani and Orvaschel (1990) found that anxiety disorders were the most common form of psychopathology reported by a community sample of children and adolescents across three age groups (eight, 12, and 17 years). These researchers reported that 25.7% of the eight-year-old children, 15.7% of the 12-year-olds, and 21.4% of the 17-year-olds met diagnostic criteria for an anxiety disorder. It is important to note, however, that the estimates reported in this study are typically criticized as being excessively high relative to those figures reported in other epidemiological investigations. For instance, in a general sample of nearly 800 pediatric patients aged seven to 11 years, Costello (1989) found that 8.9% met diagnostic criteria for at least one anxiety disorder, while Kashani and Orvaschel (1988) found that in a representative sample of 150 adolescents aged 14 to 16 years, 17.3% met diagnostic criteria for at least one anxiety disorder, and 8.7% met diagnostic criteria *and* exhibited dysfunction warranting treatment. In another major epidemiological study, conducted in New Zealand, McGee et al. (1990) reported the prevalence rate of any anxiety disorder among their sample of almost 1000 adolescents was 12.6%, making anxiety disorders the most prevalent disorder for this age group.

With respect to specific diagnoses, Kashani and Orvaschel (1990) reported that 12.9% of all children and adolescents in their nonreferred community sample met diagnostic criteria for separation anxiety disorder. Across the three age groups, the prevalence rates were: 18.6% of the eight-year-olds, 8.6% of the 12-year-olds, and 11.4% of the 17-year-olds. Costello (1989) found that approximately 4% of children aged seven to 11 met criteria for separation anxiety disorder, and Anderson, Williams, McGee, and Silva (1987) reported a prevalence rate of 3.5% for the 11-year-olds in their sample. In a follow-up of this same sample four years later, McGee et al. (1990) found that 2% of 15-year-olds met diagnostic criteria for separation anxiety disorder, while Kashani and Orvaschel (1988) reported a rate of 0.7% for the adolescents in their sample. Within a sample of children referred to an anxiety disorders clinic, separation anxiety disorder was the most common primary diagnosis, with a prevalence rate of approximately 33% (Last et al., 1987). Within this diagnosis, females tend to be overrepresented (across their three age groups, Kashani and Orvashel (1990) reported that 21.0% of girls, compared with 4.8% of boys, met diagnostic criteria for separation anxiety disorder), as do younger children, and Caucasian children from lower socioeconomic backgrounds. Further, an epidemiological study conducted by Velez, Johnson, and Cohen (1989) identified lower socioeconomic status as a risk factor for the development of separation anxiety disorder.

Prevalence rates for avoidant disorder tend to be somewhat lower than for either of the other two anxiety diagnoses of childhood and adolescence. Costello (1989), for instance, reported that 1.6% of children aged seven to 11 met diagnostic criteria for avoidant disorder. Also relevant here are prevalence rates for social phobia, which replaces avoidant disorder in *DSM-IV*. Kashani and Orvaschel (1990) reported that 1.0% of their total sample met criteria for this diagnosis. Across the three age groups, the rates were as follows: 0.0% of the 8-year-olds, 1.4% of the 12-year-olds, and 1.4% of the 17-year-olds. These authors also reported an even gender ratio for the diagnosis of social phobia—across the three age groups, 1.0% of boys and 1.0% of girls met criteria.

For overanxious disorder in children, the prevalence rates range from 2.9% (Anderson et al., 1987) to 4.6% (Costello, 1989), while 7% of adolescents have been reported to meet criteria for the diagnosis (Kashani & Orvaschel, 1988). Kashani and Orvaschel (1990) reported that 12.4% of their total sample met criteria for overanxious disorder, with the age breakdown being as follows: 8.6% of eight-year-olds, 11.4% of 12-year-olds, and 17.1% of 17-year-olds. As can be seen from these figures, this disorder seems to occur more frequently in older children. Within a clinically anxious sample, approximately 15% had a primary diagnosis of overanxious disorder (Last et al., 1987). In terms of the gender ratio, males and females appear to be equally represented within this diagnosis, until adolescence when there is female predominance (Werry, 1991). Finally, it appears that Caucasian children from middle and upper class families may be overrepresented in overanxious disorder (Last et al.), although this finding may well reflect referrals rather than prevalence.

Thus, while available data on the prevalence of anxiety disorders are somewhat discrepant in terms of specific rates of the various subcategories of anxiety disorders, they are unanimous in pointing to ubiquity and significance of anxiety problems in general throughout childhood and adolescence. Clearly, anxiety problems emerge as the most common form of psychological distress when the children and adolescents are asked themselves.

5.13.2.4 Etiology

It would be impossible to review all theories of all types of childhood anxiety in this chapter. Thus, we limit the scope in order to cover the major etiological positions that have been translated into contemporary clinical practice. These include psychodynamic, social learning, family systems, and biological theories of anxiety.

5.13.2.4.1 Psychodynamic

Freud's (1909) description of a phobic disorder in a five-year-old boy was the first time psychoanalysis was applied to a childhood disorder, and remains a seminal documentation of the psychodynamic approach to anxiety disorders. The child had phobias of horses and of leaving the family home and Freud interpreted these as stemming from Oedipal conflicts. The boy had witnessed a horse fall violently in the street. To Freud, the horse's violent struggles brought the boy's unconscious wishes to be violent toward his father to the conscious mind, thus provoking considerable anxiety. Thus, in the psychoanalytic approach the feared stimuli are seen as being secondary to the internal stimuli that they represent. Any number of unconscious conflicts can be associated with anxiety problems; the Oedipal conflict is but one example. The common element is that anxiety results from the conscious mind being overwhelmed by uncontrollable, threatening stimuli. While these stimuli can emanate from external sources, these rarely cause clinical anxiety states. Anxiety that arises from uncontrollable, threatening stimuli coming from the unconscious mind is more likely to cause disabling clinical anxiety states. For the child, focusing on external stimuli as feared objects is seen as functional in eliminating the true source of the anxiety from consciousness.

Uncontrolled case studies have claimed effectiveness using psychodynamic methods with anxious children (e.g., Le Roy & Derdeyn, 1976). However, controlled studies have produced equivocal results (e.g., Milos & Reiss, 1982) and, overall, these methods have received little empirical support. Other problems with the psychodynamic approach have been thoroughly discussed elsewhere (e.g., King, Hamilton, & Ollendick, 1988) including difficulty evaluating theories and therapies because of a lack of specificity of definitional constructs, and the length of time needed to implement treatments. Notwithstanding, there are aspects of psychodynamic theories of anxiety that warrant recognition and further attention. First, they alert us to the common developmental aspects of fear. That is, certain fears and anxieties come to the forefront of experience at specific biologically determined phases of life. For example, separation from caregivers is one of the first fear-provoking situations that both children and parents must successfully negotiate. Second, many contemporary psychodynamic models emphasize the role of interpersonal processes in the development and maintenance of anxiety states. For example, Kohut's (1971) and Mahler's (1968) work on object–self relations emphasize the importance of early parent–child relationships in the development of stable and robust self structures that promote psychological health. Bowlby's work on attachment processes provides a well-developed theoretical and methodological model describing attachment/separation processes throughout life development, and will be discussed later in this chapter. Third, in terms of processes of internalization leading to healthy self structures, contemporary psychodynamic models share much in common with modern information-processing models of anxiety in their emphasis on intrapsychic, even unconscious, processes that lead the sufferer to attend to and overinterpret threat stimuli, both internal (e.g., physiological arousal, dangerous thoughts) and in the external environment (e.g., criticism) (see Brewin, 1987).

5.13.2.4.2 Biological

A good deal is known about the neurophysiology and endocrinology of immediate "fight or flight" reactions to noxious stimuli (Gray, (1988). However, very little is known about the biological mechanisms involved in anxiety states that are more diffuse over stimulus conditions and time. At present, there are several lines of inquiry that may shed light on possible biological bases of anxiety. A recent review by Rutter et al. (1990) of genetic transmission studies indicated that a familial loading is evident for adult anxiety disorders. However, it is impossible to discern from available evidence whether the transmission is via genetic or environmental factors. For childhood anxiety disorders, the picture is even less clear and less adequately researched. While there appears to be a familial transmission of anxiety disorders in children, it is not clearly a genetic phenomenon and it does not show disorder specificity. That is, anxious children often have parents with a range of psychiatric disturbance, and anxiety problems in parents are associated with a similarly broad range of disturbance in their children (Rutter et al.).

Research has indicated that vulnerability to anxiety varies across individuals and is stable across time. With rhesus monkeys, Suomi (1986) has shown that certain individuals are more likely than others to respond to "challenge" situations with fear and behavioral inhibition. This vulnerability appears to be traitlike, existing at relatively high frequencies in genetic as opposed to environmental (adopted) siblings, and stable over time. Further, Suomi, Seaman, Lewis, Delizio, and McKinney (1978) demonstrated that imipramine reduces these fear reactions in vulnerable individuals during separation from parental figures. Similarly, Kagan, Reznick, and Snidman (1988) have shown that the traits of "behaviorally inhibited" infants are stable over time and consistently emerge when the infant is placed in a stressful situation. More recently, Biederman et al. (1990) compared two samples of children who had been classified as either inhibited or not inhibited/uninhibited, with a view to investigating whether behavioral inhibition is associated with anxiety in children. The results indicated that a wide range of internalizing and externalizing disorders were more prevalent in inhibited children compared with the not inhibited and healthy control children. Although this study was exploratory, the data suggest that behavioral inhibition to the unfamiliar may be one of the multiple risk factors implicated in the development of childhood anxiety disorders. More recent research has examined factors that may determine which behaviorally inhibited children are at risk of developing childhood anxiety disorders. Hirshfield et al. (1992), for instance, demonstrated that the association between childhood anxiety disorders and behavioral inhibition appears to be accounted for by those children who have stable behavioral inhibition (i.e., children who remained behaviourally inhibited at each of the follow-up points). More specifically, Rosenbaum et al. (1992) reported that greater anxiety loading in the parents increased the risk for anxiety disorders in behaviorally inhibited children.

A number of theories of anxiety that attempt to bridge behavioral and biological dimensions have been put forward, particularly with regard to inherited autonomic reactivity and conditionability (e.g., Gray, 1988); however the nature and function of biological mechanisms underlying anxiety disorders remain elusive and controversial. Further research cooperation between biologists and behaviorists is sorely needed.

5.13.2.4.3 Learning mechanisms

Modern behavioral conceptions of anxiety disorders emphasize conditioning and social learning processing in both the origins and maintenance of anxiety (Davey, 1992; Graziano, De Giovanni, & Garcia, 1979; King et al., 1988; Morris & Kratochwill, 1983; Mowrer, 1960; Thyer & Sowers-Hoag, 1988). Classical conditioning processes are invoked to explain how previously neutral stimuli (e.g., public transport) become threatening through association with unconditioned aversive stimuli (e.g., being lost, abandoned, fainting, or dying). Avoidance behavior, which is negatively reinforced by the reduction in anxiety it produces, maintains the fear by not allowing any natural extinction of the fear response to occur. Operant factors, such as reinforcement from significant others and avoidance of unpleasant responsibilities may also help maintain the fear. Such learning can be direct or vicarious, that is, acquired simply by observing the person's experience of fear, and is cognitively mediated. Cues that elicit fear can be regarded as information that is processed by individuals. Thus, cognitive processing mechanisms can be seen as an important link in the fear response. In adults, measures of cognitive processing of threat information discriminate between people with anxiety disorders and others (Rapee, 1991), and more recent research has indicated similar findings with anxious children (Barrett, Rapee, Dadds, & Ryan, 1996; Vasey, 1993). Anxiety disorders, especially the social types, may be in part maintained by social skills deficits in the child. If social interactions are repeatedly unsuccessful or unpleasant for the child, they are increasingly likely to avoid or to feel anxious in such situations. Hence, social skills interventions have become an important part of behavioral approaches to child anxiety (Graziano et al., 1979; King et al., 1988).

5.13.2.4.4 Stressful events

Anxiety states in children can be associated with exposure to both acute and chronic stressors such as loss of a parent, divorce, school failure, sexual and physical abuse, and physical illness. However, the increased occurrence of environmental stressors appear to precede the onset of nearly all psychiatric disorders and even physical illness (Goodyer, 1990). Much of the effect of environmental stressors are mediated through their effects on parent–child relations. For example, many of the deleterious effects of divorce on children are associated with changes in daily routine, discipline practices, and parent–child communication (Emery, 1982). While it is clear that stressors can produce anxiety in children (e.g., Dadds & Powell, 1991) it is not clear whether this also applies to clinically significant anxiety disorders in children who already had some vulnerability or disturbance predating the stressor (Goodyer, 1990).

5.13.2.4.5 Family processes

In research up until the 1970s, reviewed by Hetherington and Martin (1979), mothers of anxious children were consistently described as domineering, overprotective, and overinvolved with the child. However, as Hetherington and Martin also noted, this image of the overprotective mother and the highly structured family system were based on "rather indirect sources of data" (p. 61). Empirical studies were more limited in the support they provided for family factors, but included elevated levels of anxiety in the parents of anxious children (Bernstein & Borchardt, 1991), and marital conflict as a correlate of anxiety in nonclinic children (Dadds & Powell, 1991). However, more recent samples of anxious children found they were not different from other groups on marital conflict or dimensions of family functioning measured by the FACES scale (emeshment, adapatability). Further, Green, Loeber, and Lahey (1992) found no evidence for the presence of deviant family hierarchies, as predicted by family systems theory (Haley, 1976; Minuchin, 1974), in the families of overanxious boys. A study by Stark, Humphrey, Crook, and Levis (1990) showed that anxious children saw their families as less supportive, less sociable, more conflictual, and more enmeshed than nonclinic children. However, the results were even more striking for depressed and mixed depressed/anxious children and so these factors are unlikely to be specific correlates of childhood anxiety.

More impressive data has come from direct observational studies of social learning processes. Krohne and Hock (1993) argued that a child's competencies are related to the parents' tendency to help the child develop problem-solving and coping skills, and, inversely, to overly control the child (restriction). The idea of parental overcontrol has often been related to anxiety problems in children. Solyom, Silberfeld, and Solyom (1976) reported that mothers of agoraphobic patients scored significantly higher on measures of maternal control than mothers of normals. Krohne and Hock (1991) found that the mothers of high-anxious girls were judged by independent observers to be more restrictive than mothers of low-anxious girls during a common problem-solving task. Similarly, Dumas, LaFreniere, and Serketich (1995) observed parent interactions among aggressive, anxious, and nondistressed dyads. The anxious dyads were characterized by high parental control and aversiveness. According to Krohne and Hock, consequence expectancies on the other hand are related to the consistency of positive and negative feedback from parents. Kohlmann, Schumacher, and Streit (1988) found significant positive associations between parental inconsistency and trait anxiety in the child.

A more recent study has indicated that parents of anxious children may differ from other parents in terms of the way they teach their children to interpret and respond to ambiguous threat cues. Barrett et al. (1996) demonstrated that anxious children and their parents make relatively high numbers of threat interpretations and, hence, choose avoidant solutions when faced with ambiguous hypothetical social problems. As part of their experimental procedure, Barrett et al. also asked the families of anxious, aggressive, and nonclinic children to discuss how their child should deal with these ambiguous situations. For anxious children only, the likelihood that the child would devise an avoidant solution increased after the family discussion. It appears as if the family process can facilitate expression of the child's vulnerabilities. In a follow-up paper, Dadds, Barrett, Rapee, and Ryan (1996) analyzed the contingent stream of family behaviors that had been videotaped in the family discussions in the Barrett et al. study. Results showed that parents of anxious children were more likely to reciprocate avoidant solutions and less likely to encourage prosocial solutions to ambiguous social situations, than parents of nonclinic and aggressive children.

5.13.2.4.6 Recent studies of attachment processes

Attachment refers to the establishment of early intimate relationships and the internalization of these relationships as stable cognitive representations of the relation of the self to intimates throughout the lifespan (Bowlby, 1969). In the late twentieth century a number of strategies for operationalizing attachment processes have been developed, including observational measures of parent–infant bonds (Ainsworth, 1989), and self-report and structured interview measures of current adult relationships and past relationships to parents (Main, 1996). A number of manifestations of insecure attachment have been described and empirically verified, including dismissive (or avoidant, e.g., avoiding or failing to seek out intimate contact) and preoccupied (or anxious/ambivalent styles, e.g., showing distress at separation, clinging, failure to show independent exploration). Using various methods of categorizing attachment, numerous studies have been published showing that different attachment processes characterize psychologically healthy versus distressed adults and children. Clinic-referred samples of children and adults show relatively low rates of secure attachment, that is, intimate relationships marked by predictable, stable, and generous levels of care and support, compared with nonclinic samples (Main).

In general, however, it has been difficult to find specific relationships between particular forms of psychopathology and specific types of insecure attachment (see van Ijzendoom & Bakermans-Kranenburg, 1996, for a meta-analytic review). Recent improvements in the design of studies may overcome this lack of specificity. For example, Rosenstein and Horowitz (1996) found that psychiatrically hospitalized adolescents with a "preoccupied" attachment style were much more likely to have anxiety and depression problems than those with a dismissive style, who tended to show conduct problems. Clearly these results are encouraging and careful research is worth pursuing in this area. It should be noted, however, that the area still tends to be characterized by reliance on global typology categories and absence of specific descriptions of behavioral processes mediating attachment and psychopathology. This is highlighted by the DeKlyen (1996) study which showed that maternal attachment added no predictive power to the child's behavioral problems once direct observational measures of parent–child interactions were considered. Gender effects also need to be considered and more effort is needed to include fathers in this area. Cowan, Cohn, Pape-Cowan, and Pearson (1996), for example, found that mothers' and fathers' attachment styles were differentially related to internalizing vs. externalizing problems in their children. Further, few treatment developments from an attachment perspective have been subjected to controlled outcome and process studies.

5.13.2.4.7 Family systems theories

While there are several varieties of theoretical approaches that fall under the general banner of family systems theory, the common thread is the notion that the family system can be viewed as a functional or homeostatic unit. Disturbance in one family member (the "identified patient") is seen as part of a disturbed family system (Barnes, 1985). At extremes, the identified patient's problems are seen as a symptom that serves to maintain homoeostatic balance in an otherwise dysfunctional family. As an example, a child's separation anxiety may be seen as providing a parent with the feeling that they are needed, thereby reducing the likelihood that marital conflict will erupt over a distant, nonintimate marital relationship. Family systems theories have been quickly translated into clinical practice and have arguably been the "boom" therapy in the late twentieth century. Unfortunately, research into the conceptual validity and treatment efficacy of these approaches has lagged dramatically behind their enthusiastic translation into clinical practice. Despite repeated calls for these approaches to be evaluated, very little empirical work has been undertaken, and thus it is difficult to support any further expansion of these family systems models at this time.

5.13.2.5 Developmental Course

As already noted, for the majority of children and adolescents, fears and anxieties are typically common, functional, and transitory. For this reason, both clinicians and parents often view childhood anxiety as a passing complaint (Keller et al., 1992). Unfortunately, for a significant proportion of all children and adolescents, this is not the case and the prognosis, if they do not receive treatment, is much less encouraging than has previously been thought. For instance, in one study, 70.6% of children aged six to 12 years who had been diagnosed with overanxious disorder were found to have retained this diagnosis at two-year follow-ups (Pfeffer, Lipkins, Plutchik, & Mizruchi, 1988). Keller et al. assessed past and present psychopathology in 275 children and adolescents aged six to 19 years who had been recruited as part of a risk study. Fourteen percent of the children were found to have a history of an anxiety disorder, and of these children only 34% were anxiety diagnosis-free at the time of the assessment. The average duration of the disorder to the time of interview was four years, but the Kaplan-Meier estimates indicated that 46% of the children with an anxiety disorder would still be ill eight years after the onset of the disorder. Keller et al. concluded by noting that "anxiety disorders in childhood may be more chronic than previously believed . . . anxiety disorders in children may be severe and enduring" (p. 598).

The chronicity of childhood anxiety would seem to be due, at least in part, to the tendency of anxiety to be associated with general social problems such as negative self-image, dependency on adults in social situations, comparatively poor problem-solving skills, unpopularity, and low rates of interaction with peers (Kashani & Orvaschel, 1990; Messer & Beidel, 1994; Panella & Henggeler, 1986; Rubin & Clark, 1983; Strauss, Frame, & Forehand, 1987). In clinical samples, anxious children are less successful in peer relationships than their nonreferred counterparts (Edelbrock, 1985; Puig-Antich et al., 1985; Strauss, Lahey, Frick, Frame, & Hynd, 1988). As a whole, this research indicates that anxiety in children and adolescents (in both clinical and nonreferred samples) is associated with significant psychosocial difficulties. Regardless of the casual direction of the relationship between anxiety and its psychosocial correlates, it makes sense to hypothesize that for many anxious children and adolescents, this relationship is one in which anxiety continually strengthens the psychological factors and vice versa, thus contributing to the chronicity of anxiety in children and adolescents who have not received treatment.

A final point worth making in this section is that although the connection between childhood and adult anxiety is not yet clearly understood, evidence from a variety of studies indicates that vulnerability to adult anxiety may manifest itself in childhood. In support of this contention, there is increasing empirical evidence that many adult anxiety disorders originally began in childhood or adolescence (Rapee & Barlow, 1992). Retrospective accounts of adult anxiety patients frequently describe the onset of anxious symptomatology in late childhood or adolescence (Gittelman, 1984; Mattison, 1992; Thyer, Parrish, & Curtis, 1985). Klein (1964), for instance, reported that at least half of a sample of severely impaired adult agoraphobic patients had had separation anxiety and difficulty adjusting to school during childhood, while Gittelman found that a notable proportion of hospitalized agoraphobic adults reported an early history of severe separation anxiety.

5.13.3 CONCEPTUALIZATION AND CLINICAL FORMULATION

5.13.3.1 Multimodal Assessment

Available assessment procedures in childhood anxiety disorders include the use of structured clinical interviews, self-report measures, direct behavioral observations, self-monitoring of behaviors and accompanying cognitions, and physiological assessment.

The structured clinical interview used most commonly with anxious children is the ADIS (Silverman & Nelles, 1988), with a form to be used for the child and a parallel form for the parents (ADIS-C and ADIS-P). The ADIS has questions relevant to the latest *DSM* categories and facilitates acceptable inter-rater reliability of anxiety diagnoses in children (see Rapee et al., 1994; Silverman, 1991). Many other structured interviews are available (see Silverman, 1991 for a review). It should be noted that the reliability achieved from these interviews varies considerably according to the source of the information, the skills of the interviewers, the age of the interviewees, the base rate of the target disorder, and other factors. Silverman (1991), in recognizing the variability of inter-rater reliability, advises researchers to speak of reliability levels in terms specific to particular cohorts rather than as a characteristic of particular disorders or interviews. With regard to the validity of diagnoses achieved from structured interviews, there is some evidence that convergence is acceptable with standardized checklists such as the CBCL (see below). Generally, however, little research has systematically addressed the many ways in which validity can be assessed, and, at present, the validity of the interviews must be considered unknown (Silverman, 1991).

A variety of self-report measures is available. The ones that have been most utilized both in research and clinical work include the Revised Children's Manifest Anxiety Scale (RCMAS) (Reynolds & Paget, 1981), the Revised Fear Survey Schedule for Children (FSSC-R) (Ollendick, 1983), the modified State-trait Anxiety Inventory for Children (STAIC) (Fox & Houston, 1983), and parent/teacher/child ratings of general adjustment across multiple dimensions of dysfunction on screening checklists such as the CBCL (Achenbach & Edelbroch, 1991). None of the anxiety checklists produces data that correspond to the current *DSM* or *ICD* categories. The FSSC-R is used for assessing the content and spread of children's fears, the RCMAS and the STAIC produce measures of felt anxiety symptoms (e.g., physiological, worry). While the reliability of these checklists is generally good, recent research has questioned their discriminative validity. That is, they cannot discriminate reliably between different groups of clinically referred children and the differentiation of anxious and attention deficit children seems particularly problematic (Perrin & Last, 1992). Further development of self-report measures is needed, exemplified by Spence's (1996) recent attempts to develop a self-report measure with symptom domains that correspond to current diagnostic categories.

It is possible to measure fear/anxiety indirectly by measuring the behaviors that people typically engage in when faced with specific threat-related stimuli. For example, measuring the amount of time a child spends at school will provide an indirect estimate of fear of school. Used under controlled conditions, these measures are usually referred to as behavioral avoidance or approach tests (BAT). The aim of the BAT is to collect objective information about how the person reacts (dependent variable) to fear stimuli (independent variable). For example, a person who has a crippling fear of dogs may be asked to approach and stroke a dog under controlled conditions (the dog is restrained). A range of dependent measures can be taken including proximity to the dog and other behaviors hypothesized to reflect the anxiety level. BATs can be standardized or individualized. The former are most commonly used for research purposes and involve a standard series of tasks to which all subjects are exposed. In an individualized BAT, the stimuli to which each child is exposed are selected on the basis of the child's own specific fears. Naturally, this would be more useful in a clinical situation but it is also valuable in research since it would maximize the fear ratings achieved.

There are many variations on the possible uses of BATs and we present a sample to give some indication of the adaptability of these tests in their use with children. Lang and Lazovic (1963) asked subjects to approach a harmless caged snake in a laboratory and scored the subject's behavior on a three-point scale corresponding to looking, touching, and holding behavior. In other studies, the subject was asked to remain still while the feared stimulus was brought closer in graded steps by an experimenter (Murphy & Bootzin, 1973). In these tests, the dependent measure is usually the distance from the child before the child conveys that he or she does not want the feared stimulus to come any closer. Although the child is always given the power to terminate these tests, active BATs are usually preferred owing to the unpleasantness and artificiality of asking a fearful child to remain passive while another person controls the feared stimulus, and to the advantages of practicing approach behavior that comes with the use of active BATs.

While most BATs have been used with animal phobias, other creative uses have been reported, including fear of blood (Van Hasselt, Hersen, Bellack, Rosenblum, & Lamparski, 1979), the dark (e.g., Giebenhain & O'Dell, 1984; Kelley, 1976), heights (Van Hasselt et al., 1979), medical procedures (Freeman, Roy, & Hemmick, 1976), water (Lewis, 1974), and strangers (Matson, 1981). In social fears and generalized anxiety conditions, it is difficult to specify the phobic stimuli in such a way as to allow their manipulation under controlled conditions. For example, a child may avoid school owing due to a fear of having to interact with large groups of unsupervised children as would be found in a school playground. Children with generalized anxiety are fearful of new events in their lives such as taking tests, going to camps, changing classes, or having to perform, which are all difficult to operationalize for use with BATs. This limitation is important and should be the attention of creative thinking and research. In the late twentieth century, anxiety research with both adults and children has increasingly focused on the more generalized forms of anxiety disorder (generalized anxiety, overanxious disorder, panic, social fear) rather than the simple of specific phobias. Owing to the difficulty of operationizing the objects of these fears, the salience of BATs in the research literature has decreased and progress in the development and refinement of these measurement strategies has slowed to a crawl.

A number of variables may affect the validity of BATs (Borkovec, Weert, & Bernstein, 1977). Clinicians and researchers rarely use existing procedures, and thus, comparison across studies is difficult. Furthermore, a BAT is a social situation in which many variables can influence the child's behavior and yet, very little research has been conducted into the role of contextual variables (cf., Kelley, 1976; Sheslow, Bondy, & Nelson, 1982). More attention needs to be given to contextual factors in childrens' performance in fearful settings. This should be done not just so we can control these as unwanted influences. Rather, we should try to understand the role of contextual factors as a means of further understanding the developmental origins of fear itself. The BAT, as well as being used as a standardized procedure for producing fear responses, could be used for assessing the role of social influences, such as the family, on childrens' anxiety.

Direct observations of childrens' anxiety have typically been designed to record discrete child behaviors in natural settings that elicit anxiety such as during medical procedures, public speaking, or school exams. Detailed reviews of these systems can be obtained from Barrios and Hartmann (1988), Dadds, Rapee, and Barrett (1994), and King et al. (1988). The Observer Rating Scale of Anxiety (Melamed & Siegel, 1975) was designed for observing children undergoing surgery and consists of 28 discrete child behaviors which the observer scores for frequency of occurrence. These include behaviors such as "trembling hands" and "clings to mother," as well as more general distress behaviors such as "crying" and "kicks." Similarly, the Behavior Profile Rating Scale (BPRS) (Melamed, Yurcheson, Fleece, Hutcherson, & Hawes, 1978) contains 27 behaviors for use in dental settings and, thus, includes relevant behaviors such as refusing to open one's mouth. For both systems, the frequency of discrete behaviors can be combined into an overall anxiety score, although it should be noted that the overall score reflects distress and noncompliant behavior as well as anxious behavior. Further, the BPRS contains items that are scored according to the dentist's behavior, for example, the "dentist uses loud voice." Reliability and discriminative validity data have been collected and are supportive of the systems. Another observational system that has been applied to stressful medical procedures and undergone extensive development and evaluation is the Procedure Behavioral Rating Scale and its derivatives (Jay & Elliott, 1984; Jay, Ozolins, Elliott, & Caldwell, 1983; Katz, Kellerman, & Siegel, 1980; Le Baron & Zeltzer, 1984). These systems involve an observer rating the frequency of a number of child fear and distress behaviors during bone marrow procedures.

Glennon and Weisz (1978) developed a system for observing anxiety in preschool children. Their main rationale was to develop a measurement system for use with young children that avoided problems of self-report and global adult ratings. The Preschool Observation Scale of Anxiety (POSA) contains 30 behaviors that were selected to reflect fearful behavior in young children. These include both direct signs of fear ("child complains of being afraid," "trembling," "fearful facial expression"), indirect signs of fear ("cry," "gratuitous movement," "nail biting"), and other behavior selected to reflect fear in this population ("masturbation," "silence," "rigid body posture"). Glennon and Weisz evaluated the POSA in observations of preschool children's behavior during a forced separation from their mothers at their regular preschool. However, the system could be used in any setting. Inter-rater reliabilities ranged from quite low to very high, as did the frequency of the observed behaviors themselves, and further work may be required to refine the sample of 30 behaviors. The POSA represents one of the few attempts to operationalize child anxiety into an observation system that can be used in a range of natural settings. Milos and Reiss (1982) used an observation system that scores the frequency of a single global behavior as a reflection of anxiety during separation. Neisworth, Madel, and Goeke (1975) designed a system that measures the duration of crying and screaming in preschoolers during their daily preschool routine.

By far the most research and theorizing that has occurred with regard to separation anxiety has occurred within the social attachment literature. The original impetus for this area came from the intensive observations of Harry and Margaret Harlow, using infant rhesus monkeys (Harlow & Harlow, 1962), Bowlby's (1973) observations of orphaned children, and Ainsworth's observations of separated infants (Ainsworth, Blehar, Waters, & Wall, 1978). Typically, the child is observed during separation from the mother, exposure to an unfamiliar adult, and reuniting with the mother (Ainsworth et al., 1978). Research by Kagan and colleagues has shown that the infant's behavior during such challenges is predictive of the later development of anxiety and social withdrawal problems. Specifically, infants that show "behavioral inhibition" (long latency to interact with and retreat from unfamiliar adults, cessation of play and clinging to the mother) are more likely to develop social anxiety and withdrawal later in childhood (Kagan, Reznick, & Snidman, 1988).

A number of systems have also been designed to observe children's responses to test performance and public speaking. For example, Wine (1979) developed an observational system that comprises 22 discrete behaviors that are recorded over a 15-minute interval immediately preceding a classroom examination. The behaviors are grouped into attending, task-related, activity, communication, and interactional behaviors. Few of these are directly reflective of the expression of anxiety but rather focus on the indirect effects of anxiety on the child's ongoing activities. Paul's (1966) timed behavior checklist was designed to measure the presence of overt anxiety in adolescents in public-speaking situations. It has been adapted for use with younger children's reactions to public speaking (Fox & Houston, 1981) and darkness (Giebenhain & O'Dell, 1994). The original contains 20 items that are recorded for occurrence or nonoccurrence over a series of observational intervals and can be reduced to an overall anxiety score for the observation session.

Another method for measuring anxiety is to have observers use global rating scales. As examples, an observer may be asked to observe a child for a five-minute period and then rate the child's level of anxiety on a five-point scale; and, a parent of a child with fear of school may be asked to provide a similar rating every minute for the 30-minute period at home immediately prior to leaving for school. These systems are generally easy to use, but have specific advantages and disadvantages. First, research has indicated that people are generally very consistent in their observations and descriptions of the effect in other people. Even across different cultures, people tend to agree on the facial expressions that signal fear (Ekman, 1980). Thus, inter-rater reliability is generally quite high for global ratings of anxiety. A number of studies of anxious children have used such global ratings and the reader is referred to the reviews by Barrios and Hartmann (1988) and King et al. (1988). The problem with global ratings is that it is not clear exactly what is being measured and thus they generally have little to contribute to our understanding of anxiety. This restricts their use to situations in which an inexpensive and simple measure of anxiety is needed, and as with all single measures, they should be used as part of a more comprehensive assessment package (King et al., 1988).

The development of observational strategies for measuring child anxiety mostly took place in the 1960s and 1970s and, since that initial burst of activity, little has occurred in terms of the development and refinement of these methodologies. Most existing observational strategies focus solely on the child. Creative attempts to operationalize the social context of the child's anxiety and examine its functional relationship to the development of anxiety are sorely needed. Questions remain unanswered about the validity of these systems in terms of the content of the behavioral categories used. With children, most of the observational systems contain a mix of direct expressions of anxiety as an effect, as well as protest behaviors that are thought to result from anxiety. Using observation systems that lump all effect and protesting behaviors together to produce one overall "anxiety" score will not differentiate between these children. More work is needed to examine whether it is psychometrically and conceptually sound to treat these various components as unitary reflections of anxiety; quite possibly they are functionally very different when one considers how they affect and are affected by their social context. The discriminative validity of these observational systems remain unclear. Very little evidence is available to indicate that these systems can differentiate anxious from nonanxious children. Further, there is no evidence to show that children with different types of anxiety problems can be differentiated. Finally, the targets of these systems are mainly restricted to simple fears that are expressed in highly structured settings. Little work has been done attempting to use observational measures with children with complex, generalized anxiety.

We believe that there is enormous unrealized potential in the use of direct observations of anxiety in young children. Two major areas for development suggest themselves. There is the need to understand the child's anxiety in terms of its social context. Thus, observation systems that score both the child's anxiety as well as other antecedent and consequent stimuli need to be developed. Also, observations need to be designed and used in a way that allows for conceptual integration with other aspects of anxiety such as cognitive processing style, family interaction, and physiological reactivity. For example, much progress is currently being made in understanding the way anxious people process information about threat in their environment (e.g., Butler & Mathews, 1983). That is, anxious people show an exaggerated tendency to perceive, attend to, and respond to threat in their environments. We may ask whether this processing style is learned through interaction with significant others, namely anxious parents. A methodology that integrates information processing and direct observation of the child in interaction with others may yield important insights into this process. The work by Krohne and colleagues (Krohne, 1992; Krohne & Hock, 1991) and Barrett et al. (1996), reviewed above, are examples of fruitful attempts in this direction.

5.13.3.2 Treatment Formulation

The treatment formulation represents the integration of the theory of etiology, a theoretically guided and multimodal assessment of the individual case, and the existing literature on the efficacy of available intervention strategies. While this will in part depend on the skills and theoretical approach of the particular clinician, a number of guiding principles can be extracted from existing knowledge.

The conceptualization of the case should include a diagnostic formulation in terms of current *DSM* or ICD systems with particular reference to the developmental and cultural characteristics of the child and the normative expression of fears and anxieties that exist in all children. As well as the normative and cultural aspects of fear, preliminary formulations should consider the likelihood that the child's fears and anxieties are realistic in context. We have assessed a number of cases of "separation" and "social" fears in which the referred child was being exposed on a daily basis to threats of removal from the family home, and bullying at school, respectively. As previously stated, multiple informants should be used in gathering these data.

Factors hypothesized to be implicated in the development and maintenance of the anxiety problem should include a thorough examination of the following:

(i) Social learning factors: the extent to which the child experienced a learning history predictive of conditioned or traumatic responses to previously neutral stimuli, and what operant factors are currently maintaining a pattern of avoidance and anxious responding.

(ii) Cognitive factors: the extent to which the child shows a pattern of negative competency and outcome expectancies, low self-esteem, and over- or selective attention to potential threat in the environment.

(iii) Physiological factors: the extent to which the child exhibits physiological arousal (muscle tension, problem breathing) associated with avoidance and anxiety.

(iv) Family factors: the extent to which the child has stable, nurturing family relationships, and the extent to which the other family members have anxiety problems.

(v) Peers and social skills: the extent to which the child has the skills and opportunities to develop appropriate and pleasing peer relationships.

Using an assessment and therapy procedure that empowers the child and family in terms of acquired knowledge, skills, and decision making, the above factors should be summarized into a concise formulation and treatment plan that clearly prioritizes and addresses the relevant causal factors. The treatment plan will thus usually involve some combination of social learning interventions such as: exposure, modeling, and reinforcement for overcoming avoidance; cognitive skills for the child such as positive self-talk, developing positive expectancies, attention to nonthreat stimuli, and reinforcing oneself for success; relaxation, breathing retraining, and other skills for overcoming uncontrollable and unpleasant physiological arousal; a family intervention to establish other family members as positive models of courage and social competence, as sources of stable care and nurturance, and sources of reinforcement for success; and social skills and school interventions to facilitate positive peer relationships and remove any sources of (realistic) fear from the school setting.

The treatment formulation should specify clear goals for improvement that are graduated from easy to difficult so the child has early success and a growing sense of mastery. The active involvement of family members is important, especially for children in the preteenage years.

5.13.4 TREATMENT

5.13.4.1 Psychosocial Treatments

Psychodynamic and systemic therapies have been used in the treatment of childhood anxiety disorders; however, the lack of controlled studies prohibits conclusions about their usefulness. However, there have been some preliminary studies of psychodynamic treatments for childhood disorders. For example, although the studies by Milos and Reiss (1982) and Target and Fonagy (1994) do not allow conclusions about differential efficacy, they offer some hope for the use of empirical procedures with psychodynamic therapies. Hopefully, the early years of the twenty-first century will see these methods come under the scrutiny of careful research designs. In the following, we focus on cognitive-behavioral, family, and pharmacological treatments that have been evaluated, followed by a review of the main treatment outcome studies related to specific diagnostic groups.

In terms of cognitive-behavioral interventions, King et al. (1988) and Ollendick and Francis (1988) recommend an integrative treatment approach, encompassing exposure variants, modeling, operant, and cognitive-based procedures. Exposure techniques include the use of systematic desensitization proper (imaginal representation of the fear producing stimuli and the use of muscular relaxation as the competing inhibiting response), *in vivo* and imaginal exposure, and emotive imagery (the imagery component is used as the fear-inhibiting agent). An advantage in using these techniques is the clarity of procedural guidelines available to the therapist. Still controversial is the issue of what underlying mechanisms account for the success of exposure-based procedures. Originally, Wolpe (1958) explained it as reciprocal inhibition of anxiety through relaxation. However, numerous case studies have been reported wherein the relaxation had little effect on treatment outcome. More recent views conceptualize the changes during exposure treatments in terms of information-processing changes (Foa & Kozak, 1986). Implosion and flooding-type treatments are not usually used with children owing to the potential aversiveness of the procedures involved.

Modeling procedures include the use of films, *in vivo*, or participant-modeling variants. The child is prompted to imitate the performance of the model who is demonstrating nonfearful behaviors and is reinforced for closer approximation to the coping behavior. Modeling can provide an opportunity for both the vicarious extinction of a child's anxiety, and an acquisition of more accurate information and effective coping skills relative to the anxiety-provoking situation. The efficacy of modeling procedures in the treatment of childhood phobias and in the preparation of children for stressful events has been clearly documented (Ollendick & Francis, 1988).

Operant-based programs (based on contingency management principles) have been especially successful in the treatment of school refusal, socially avoidant children, and specific phobias (King & Ollendick, 1989). Operant procedures are based on the premise that fear and anxiety will reduce when nonfearful behaviors are reinforced and fearful behaviors are placed on an extinction schedule. Within this approach, it would not be considered necessary to use methods such as relaxation to reduce anxiety directly. The child is simply reinforced for approaching the feared stimuli and rewards for fearful behaviors (e.g., parental comforting, substitution of aversive activities by pleasant play time) are removed. The evidence for the efficacy of operant programs comes mainly from case studies with phobic children, and in general therapeutic success is enhanced when operant procedures are combined with other techniques (King et al. 1988; Ollendick & Francis, 1988).

Self-instruction training is the most commonly used cognitive-based procedure in the treatment of childhood anxiety (Graziano & Mooney, 1980; Meichenbaum & Genest, 1980; Meichenbaum & Goodman, 1971). It is aimed at changing the child's self-talk on the premise that self-doubting and negativistic self-talk increases anxiety and inhibits appropriate responses to feared stimuli. Basically, the child is taught to use competence-mediating statements in the presence of the anxiety-provoking stimuli. However, cognitive procedures alone are often not effective in overcoming anxiety reactions in children owing to the multiplicity of factors involved, such as environmental contingencies, skills competencies, individual developmental factors regarding awareness and identification of self-statements, and the strong physiological component of anxiety disorders.

The integration of cognitive and behavioral procedures in the treatment of childhood anxiety disorders seems to be largely supported in the literature. However, most of the studies previously described have focused on the treatment of specific phobias using single case designs. Evaluative studies on the treatment of separation anxiety, avoidant, and overanxious disorders were less evident. However, in recent years, a number of controlled trials have demonstrated the effectiveness of protocol-based psychosocial interventions that are applicable across various categories of child and adolescent anxiety disorders. Blagg and Yule (1984), working with a total of 66 children presenting with fear of school and separation from parents, examined treatment outcome associated with behavioral therapy, hospitalization, and psychotherapy plus home schooling. The behavior therapy program incorporated exposure to the school setting and contingency management implemented by both parents and teachers. Both at post-treatment and one year follow-up, separation anxiety symptomatology was absent in the behavioral therapy group but still present in the hospitalized (33.3%) and psychotherapy (94%) groups. Average duration of treatment was two weeks for behavior therapy, 45 weeks for hospitalization, and 72 weeks for psychotherapy plus homeschooling.

In the first controlled trial for mixed groups of anxious children, Kendall (1994) evaluated the effectiveness of a 16-session cognitive-behavioral therapy (CBT) program for a group of children with overanxious, separation, and social anxiety problems. The treatment centers around having the child develop an individualized FEAR plan: *F*, for feeling good by learning to relax; *E*, for expecting bad vs. good things to happen through positive self-talk; *A*, for approaching actions to take in the face of fear; and *R*, for rewarding oneself for efforts to overcome fear or worry. Compared with a waitlist control, the treated children showed clinically significant gains that were maintained at one year follow-up. Follow-up studies have replicated these positive outcomes (Kendall et al., in press) and shown that the treatment effects were maintained to follow-up assessments conducted an average of 3.5 years after treatment (Kendall & Southam-Gerow, 1996).

An issue raised by Kendall (1994) concerned the role of the family in these CBT programs. His recommendation was that active parental involvement is useful for positive child outcomes. More family systemic and psychodynamic theorists would argue that change in the family system would be critical to real change in the child's problem and, at extremes, that solely changing anxiety symptoms in the child without focusing on underlying family dynamics, would be counterproductive. This issue was addressed by Heard, Dadds, and Conrad (1992) in a study researching the effects of a cognitive-behavioral intervention for childhood anxiety on family variables. They treated three adolescents presenting with simple phobias using contingency management, exposure, and self-instructional training. A multiple baseline design across subjects was used. Results showed marked improvement (at post-treatment and three months follow-up) in anxiety both at overbehavioral and cognitive levels for all three adolescents. Despite sole focus on the child's anxiety symptoms, no negative or compensatory effects on family process, or individual or dyadic adjustment in other family members were observed. Thus, they found no evidence for the family systems hypothesis that treating anxious children using solely child-focused behavioral techniques leads to negative consequences for the rest of the family system.

A recent controlled trial assessed the efficacy of involving parents of anxious children in a CBT program. Barrett, Dadds, and Rapee (1996) compared a CBT intervention based on Kendall's (1990) anxiety management program to an intervention that included the CBT intervention plus a family intervention, again for a mixed group of overanxious, separation anxiety, and socially phobic nine to 14-year-olds. Parental sessions introduced parents-to-child management skills (reinforcement skills, planned ignoring, giving, and backing up clear instructions) and how to use these skills to manage their child's anxiety, explained what the children were learning in the CBT program and illustrated how parents could model and encourage the use of strategies learned in the session, and showed parents how they could use the same strategies, that is, Kendall's FEAR plan, to manage their own anxiety. Evaluation of the program at the end of treatment revealed that 61% of children in the CBT group no longer met a *DSM-III-R* diagnosis, compared with 88% in the combined treatment. Less than 30% were diagnosis free in the waitlist control group. At 12 months follow-up, the relative superiority of the CBT plus family condition was maintained. Thus, it appears that the modification of parental skills can have a significant effect on anxiety in children when combined with a CBT program for the child. However, it is not clear whether a change in parental skills on its own will result in an improvement in child behavior, and it is not clear which aspect of the parental intervention was associated with the extra improvements.

Barrett (1995) showed that similar success rates could be achieved by presenting the combined CBT-family treatment in a group format to anxious children and their parents, thereby significantly reducing costs of intervention. Cobham and Dadds (1995) used the same group intervention to assess the role of parental anxiety in treatment outcome, and the extent to which the second component of Barrett et al.'s (1996) family treatment (parents skills for managing their own anxiety) could alleviate putative poorer treatment outcomes associated with high parental anxiety. Results indicated that high parental anxiety was a risk factor for poorer treatment outcomes for anxious children, and that specifically targeting parental anxiety for intervention could overcome this risk factor in the context of a cognitive-behavioral program for the child.

The above brief review indicates that anxiety disorders in late childhood and early adolescence can be effectively treated in the majority of referred cases. However, early intervention and prevention programs aimed at larger cohorts of children have the potential to be even more cost effective in reducing the incidence of childhood disorders and their cost to the community. A number of authors (e.g., King, Hamilton, & Murphy, 1983; Spence, 1994) have discussed the potential of such programs for children at risk for anxiety disorders. The Queensland Early Intervention and Prevention of Anxiety Project (Dadds, Spence, Holland, Barrett, & Laurens, 1997) utilized a school-based sample of 1786 seven- to 14-years olds. 9.7% of children were identified by teachers as having anxiety problems. A separate group (10.5%) scored 20 or above on the RCMAS. Only 2.0% were both nominated by teachers and scored above 19 on the RCMAS. *Post hoc* analyses showed that the low convergence between teachers' and children's reports may have been due in part to the tendency of some children not to report their anxiety, possibly owing to social desirability factors.

At the conclusion of a diagnostic interview, those children who fell within the "at risk" selection criteria were allocated to the intervention or monitoring condition on the basis of treratment vs. monitoring schools. The intervention was based on the Barrett study (1995) except that it was presented in group format in 10 sessions. On average, children attended over eight of the 10 child intervention sessions, mothers attended 1.7, and fathers 0.63 of three parent sessions. At pretreatment, approximately 75% of children interviewed met criteria for an anxiety diagnosis. At postintervention, improvement was noted for both intervention and monitoring groups. However, children who received the intervention emerged with lower rates of anxiety disorder at six months follow-up compared with those who were monitored only. Of those who had features of disorder, but no full disorder at pretreatment, 54% progressed to a diagnosable disorder at six months follow-up in the monitoring group compared with 16% in the intervention group. These results indicated that the intervention was successful in reducing rates of disorder in children with mild to moderate anxiety disorders, as well as preventing the onset of anxiety disorders in children with early features of a disorder.

5.13.4.2 Pharmacological Treatments

Medication is rarely used as the sole treatment for anxiety disorders in children and adolescents, but instead is typically one part of a treatment program (Allen, Leonard, & Swedo, 1995; Bernstein, 1994). Psychopharmacological interventions tend to be implemented more commonly with older children and adolescents, and also in cases where anxiety symptoms are particularly severe and resistant to other forms of treatment. Unfortunately, there are comparatively few studies that have attempted to evaluate the efficacy of psychopharmacological interventions with anxious children and adolescents. In addition, methodological shortcomings often make results equivocal or difficult to interpret, including small sample sizes, use of samples with mixed diagnoses based on noncurrent diagnostic systems (McDaniel, 1986), concurrent treatments which are not controlled, absence of placebo control groups, and inadequate medication dosages (Bernstein, 1994). These limitations must be kept in mind when evaluating outcome studies for each class of anxiolytics to be reviewed below.

A number of studies have suggested the possible benefit of benzodiazepines in the treatment of anxiety in children and adolescents. Simeon and Ferguson (1987) found that seven of 12 participants (aged eight to 16 years) with a diagnosis of avoidant and/or overanxious disorder manifested at least moderate improvements in terms of clinician-rated symptomatology when they received between 0.5 and 1.5 mg alprazolam (tradename Xanax) per day over a four-week period. Self-report, however, did not depict any improvement in anxiety symptoms. A subsequent, four week, double-blind, placebo-controlled study with a group of 30 children and adolescents (aged eight to 16 years) diagnosed with either avoidant or overanxious disorder and treated with a mean dose of 1.6 mg alprazolam found greater improvement on global improvement ratings compared with participants in a placebo group, although these results were not statistically significant (Simeon et al., 1992). More recently, Graae, Milner, Rizzotto, and Klein (1994) conducted a double-blind crossover trial with 12 children (aged seven to 13 years) with various anxiety diagnoses, in which four weeks of placebo were compared with four weeks of clonazepam (tradename Clonopin; up to 2 mg per day). Although 50% of the children no longer met diagnostic criteria at the end of the trial, clonazepam was not found to produce superior results to the placebo on clinical rating scales completed at the end of the study. In other uncontrolled studies, benzodiazepine treatments have been associated with a decrease in the frequency and/or intensity of symptomatology in children and adolescents with panic disorder (Kutcher & MacKenzie, 1988), and pediatric cancer patients prior to anxiety-provoking medical procedures (Pfefferbaum et al., 1987).

Clearly, the limited research that has examined the efficacy of benzodiazepine treatment of childhood anxiety is difficult to interpret. Less equivocal is the research on side effects related to this class of anxiolytics. The consensus in clinical studies appears to be that benzodiazepines are tolerated by children with minimal side effects (Bernstein, Garfinkel, & Borchardt, 1990; Biederman, 1987; Pfefferbaum et al., 1987; Simeon & Ferguson, 1987; Simeon et al., 1992), and that when side effects do occur, they tend to be dose-related (Kutcher, Reiter, Gardner, & Klein, 1992).

Reported side effects include: ataxia (unsteady gait), diplopia (blurred/double vision), reduced mental acuity, sedation, slurred speech, tremor, drowsiness (Biederman, 1991; Kutcher et al.), and behavioral disinhibition as evidenced by oppositional behavior, liability, and irritability (Graae et al., 1994). Although this class of medication seems to be comparatively safe in overdose (Kutcher et al.), as Biederman (1991) notes, the risks associated with tolerance and dependence in children treated with benzodiazepines are unknown at this time.

As is the case with the benzodiazepines, studies of the efficacy of tricyclic antidepressants with anxious children have produced conflicting results. Four placebo-controlled studies have investigated the outcome of tricyclic antidepressant interventions in the treatment of separation anxiety or school refusal associated with separation anxiety. In the first of these, Gittelman-Klein and Klein (1971, 1973) conducted a six-week trial in which 45 children were assigned randomly to either 100–200 mg of imipramine (tradename Tofranil) per day or a placebo group. Both groups also received behaviorally oriented psychotherapy. Compared with the placebo group, the imipramine group was superior—both in terms of the number of children returning to school and symptom improvement. Using an average dose of 153 mg of imipramine per day, Klein, Koplewicz, and Kanner (1992) were unsuccessful in their attempt to replicate these results in 20 children (aged six to 15 years) with separation anxiety. In another recent study, Bernstein et al. (1990) reported that there were no significant differences among groups of children and adolescents (aged seven to 17 years) who received either alprazolam (mean dosage of 1.8 mg per day), imipramine (mean dosage of 164.3 mg per day), or a placebo. Similarly disappointing results have been reported for the use of clomipramine (tradename Anafranil) in facilitating either a return to school or a reduction in anxious symptomatology with 51 anxious children and adolescents aged nine to 15 years (Berney et al., 1981). Although only one of the four studies reviewed above provides support for the efficacy of the tricyclic antidepressants in the treatment of separation anxiety (with or without school refusal), as Bernstein (1994) notes, one of the three negative studies used an arguably subtherapeutic medication dosage (Berney et al.), while the remaining two had very small sample sizes (Bernstein et al.; Klein et al.).

The most frequent side effects of using tricyclic antidepressants with children and adolescents include blurred vision, sedation, orthostatic-induced lightheadedness, dry mouth, urinary retention, and constipation. More uncommon side effects include jaundice, agitation, lethargy, heart rhythm problems, sleep disturbance, and allergic reactions. An additional problem associated with use of the tricyclic antidepressants is that overdosage may result in severe medical complications, including delirium, seizures, and heart rhythm problems.

Recently, there has been some suggestive evidence that buspirone (tradename Buspar) may be effective in the treatment of generalized anxiety in children and adolescents. In an uncontrolled case study, Kranzler (1988) reported that a 13-year-old boy with overanxious disorder and associated school refusal was successfully treated with 10 mg per day of buspirone. More recently, however, Kutcher et al. (1992), in a study of adolescents, diagnosed with either overanxious or generalized anxiety disorder, reported that following six weeks of buspirone therapy (between 15 mg and 30 mg per day), the adolescents' ratings of anxiety on self-report measures had decreased significantly. On the basis of these studies, Allen et al. (1995) suggested that controlled trials of buspirone with this clinical group may be merited. In addition to this suggestive evidence regarding its possible efficacy in the treatment of anxious children and adolescents, buspirone is also noteworthy for its lack of major side effects, its limited potential for abuse, and its low probability of producing withdrawal symptoms following cessation (Kutcher et al.).

Fluoxetine (tradename Prozac) has shown promise in the treatment of childhood obsessive compulsive disorder (Riddle, Hardin, King, Scahill, & Woolston, 1990; Riddle et al., 1992). More recently, however, an open study examining the efficacy and safety of fluoxetine in the treatment of more generalized anxiety in children has been conducted by Birmaher et al. (1994). Twenty-one treatment-resistant children and adolescents aged 11–17 years with diagnoses of overanxious disorder, separation anxiety disorder, or social phobia received a mean fluoxetine dose of 25.7 mg per day for an average of 10 months. At the end of the trial, 17 of the 21 subjects (81%) showed moderate to marked improvement in their anxiety symptoms. Combined with the fact that there were no significant side effects, these results prompted the authors to suggest that fluoxetine may have potential with nondepressed children and adolescents with anxiety disorders other than obsessive compulsive disorder and panic disorder (Birmaher et al., 1994)

As Coffey (1990) notes, the efficacy of beta-blockers in children and adolescents suffering from anxiety has yet to be clearly established, and as a consequence, this class of drug is not commonly used with children. There is, however, some evidence that beta-blockers may be effective in blocking the physiological symptoms of arousal typically associated with anxiety disorders. Famularo, Kinscherf, and Fenton (1988) conducted a four-week trial of propranolol (tradename Inderal; target dosage of 2.5 mg kg^1 per day) with 11 children (mean age of 8.5 years) with post-traumatic stress disorder. The results indicated that compared with a placebo, the active medication condition was associated with a significant improvement in symptoms, and that this improvement disappeared when the medication was discontinued. Side effects of the beta-blockers include constipation, sedation, nausea, hypotension, diarrhoea, bradycardia, increased airway resistance, vomiting, and depression. Kutcher et al. (1992) caution that this class of anxiolytics should be used only with treatment-resistant patients who are experiencing situational anxiety, and that if the beta-blockers are to be considered for use, the child or adolescent for whom they have been prescribed should be strictly monitored by medical staff.

Overall there is a lack of well-controlled and well-conducted research study into psychopharmacological interventions, and there is little support for them as sole treatments for anxiety disorders in children and adolescents. There may be a place for them in the treatment of this clinical population as an adjunct to other programs (such as behavioral, cognitive-behavioral, or psychotherapeutic interventions) but more research is needed. Of the various classes of anxiolytics reviewed here, the benzodiazepines have received the most empirical support, thus warranting their position as the medication most commonly prescribed for anxiety-disordered children and adolescents.

5.13.5 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

So much needs to be done in the area of childhood anxiety disorders that we will limit our suggestions to a few broad areas. First, the relationship between child development and anxiety disorders remains relatively unexplored and the developmental course of anxiety problems needs to be clarified using longitudinal studies of large cohorts. Second, the validity of current diagnostic systems is uncertain and this makes definitive research into etiology and prognosis difficult. Third, measures that can clearly differentiate between anxiety and other childhood disorders, and between different types of child anxiety disorder are sorely needed. Fourth, experimental studies that integrate different putative causal mechanisms are needed. That is, studies need to measure social learning, cognitive, interpersonal, and biological aspects of anxiety concurrently before more comprehensive models of etiology can be developed and tested. Each of these aspects of anxiety seems important, but with researchers only considering one or two at a time, it is difficult to discern their relative and interactive importance in etiology. Fifth, evidence is emerging that psychosocial treatments are quite efficacious with clinically referred anxious children. Further, a recent study indicated that such treatments have the potential to be used in school settings as preventive interventions. Further research is needed to explore the effectiveness of these treatments across a range of clinical and community settings. Sixth, existing research into pharmacological interventions is scarce, poorly controlled, and rarely assessed concurrently with psychosocial interventions. Their efficacy needs to be assessed as does their community effectiveness and social validity.

Finally, as noted earlier three theoretical models of the development of anxiety disorders have credible explanatory power and at least limited empirical support: social learning theory (SLT), attachment theory (AT), and biological models such as Kagan's inhibition model. There may be a number of potential benefits to be made by contrasting and possibility integrating their complementary strengths and weaknesses. For example, in its purest forms, SLT takes all stimuli as equal in potential to elicit fear and has little to say about the biological and development relevance of various stimulus settings. By contrast, AT recognizes that particular settings may be potent for learning fear vs. courage, such as the parents' and child's first experiences of separation and reunion. Conversely, AT places little emphasis on the microprocesses that establish and maintain behaviors, or the methodologies by which these microprocesses can be examined under controlled conditions. SLT has a rich and successful history in these domains. The two models make predictions that are seemingly contradictory, at least in terms of our current understanding with respect to the development and expression of fear. For example, SLT would predict that contingent parental soothing should reinforce fear displays, and punishment of fear responses should suppress them. By contrast, AT predicts that parental soothing will facilitate the child's skills in self-soothing, leading to a decrease in future fear displays, whereas punishment of fear responses will lead to an insecure attachment and an increase in fear behavior. This raises the exciting possibility that critical experiments could be designed to compare and contrast these predictions. Attempts at integration have potential beyond simply watering down each model to find facile similarities between the two. Interesting attempts in this direction have already begun: for example, Brewin's (1987) argument that Bowlby's attachment model is complementary to contemporary cognitive models of how self-structures are internalized in anxiety and depressive disorders appears fruitful.

5.13.6 SUMMARY

Humans have an inherent capacity to react to threat stimuli with fear and anxiety. The strength of this reaction varies across individuals and with the nature of the stimulus. Important aspects of anxiety disorders include developmental factors, in that normal developmental tasks predispose humans to different anxieties at different times of life. Within this developmental framework, considerable explanatory power is afforded by classical, operant, and social learning processes in both the origins and maintenance of child anxiety; and by variability in individual's susceptibility to react to stressful challenges with behavioral inhibition, anxiety and fear vs. disinhibition, impulsivity and aggression. The latter appear to be reasonably stable traits; however, the genetic and/or biological mechanisms underlying these processes are not understood. Recent developments in cognitive theory and research have shown that anxious people may process information in a way that increases the salience of threatening cues and catastrophic implications in their environment, but most of this work has been conducted with adults. With children, social contexts may be especially important to adjustment, and converging evidence suggests that high levels of control, restriction, attention to social threat, and endorsement of avoidant coping strategies are characteristic of families of anxious children.

Epidemiological studies indicate that anxiety disorders are the most common form of child and adolescent psychological problem. More tentative evidence indicates that these problems may, in their severest forms, be disabling and chronic and may have some continuity with adult anxiety problems. Anxiety is a very difficult phenomenon to measure in ecologically meaningful ways. To operationalize a person's ability to approach a snake in a laboratory is reasonably simple. However, to operationalize more complex forms of anxiety, such as generalized anxiety and panic, and then measure them in real-world situations is currently beyond our scope of knowledge and technology. Thus, the common but generalized forms of anxiety remain elusive to observational strategies, and the discriminative validity of existing self-report measures is poor. Progress has occurred in diagnostic systems but the validity of these remains controversial.

Social learning, cognitive, interpersonal, and biological models of etiology all seem to have some explanatory power but their relative and interactive importance is unknown as most research has considered them in isolation. Perhaps the most salient progress that has occurred over in the late twentieth century is the development and evaluation of cognitive-behavioral and family treatments. These appear to be highly efficacious with a broad range of clinically referred anxious children. The efficacy of drug treatment with any of the common childhood anxiety disorders remains a speculative issue. The broader community effectiveness and social validity of existing treatments remains unknown; however, there is some evidence that social learning therapies may have the potential to be used as early and preventive interventions in school settings.

5.14.1 DEFINITION AND PHENOMONOLOGY

A specific phobia (SP) is a persistent and excessive fear in the presence of, or in anticipation of, a circumscribed object or event (*DSM*; American Psychiatric Association, 1994). Unlike a "normal" nonclinical fear, an SP usually leads to extreme avoidance of the fear-provoking object or event, resulting in severe distress and interference in the daily functioning of children and their families. For example, children with an SP of dogs may not leave their home to avoid a possible encounter with a dog; children with an SP of sleeping alone in the dark may insist that their parents sleep along with them; children with an SP of medical procedures (such as injections) may refuse to go to doctors' appointments or to hospitals. Also, in contrast to children's normal fears, SPs are usually out of proportion to reality and do not dissipate by reassurance, reason, or information.

In referring to phenomonology, it has become common to focus on the three-response system: behavioral, cognitive, and physiological (e.g., Lang, 1977). In terms of the behavioral system, avoidance is most common, and, as noted, typically children go to great lengths to avoid the feared object or situation. Additional behavioral manifestations include tantruming, crying, or "freezing up" when faced with the feared object or event. In terms of the cognitive system, often children report catastrophic beliefs that involve feared outcomes, particularly of physical or personal injury (e.g., "the dog will bite me," "I'll get hit by lightening"). Finally, in terms of the physiological system, manifestations include somatic complaints (e.g., stomach aches, headaches), accelerated heart rate, sweating, shakiness, and muscle tension (Last, 1991). A vasovagal fainting response occurs in a majority of children with phobias of blood-injection-injury (American Psychiatric Association, 1994; Page, 1994).

5.14.1.1 Developmental Variations

Most of what is known about developmental variations is based on research of nonpathological fears using nonclinic samples of children. Findings from this research generally show that the number and intensity of children's fears decrease with age (e.g., Eme & Schmidt, 1978; Ollendick, King, & Frary, 1989). For example, in Ollendick et al. (1989), self-ratings of fear, among a school sample of 1185 children (aged 7–16 years) residing in the US and Australia, indicated that children in the youngest age group (aged 7–10 years) reported a greater number of fears (mean number = 17) compared to children in the middle (aged 11–13 years; mean number = 13) or oldest age group (aged 14–16 years; mean number = 12). Children in the youngest group also reported a higher intensity of fears as reflected by their total fear score (mean = 138.83) compared with children in the middle (mean = 133.44) and oldest age group (mean = 129.46) (Ollendick et al., 1989).

In addition to the number and intensity of fears, research findings suggest developmental variations in the content of children's fears in nonclinical samples (e.g., Bauer, 1976; Bell-Dolan, Last, & Strauss, 1990; McGee, Feehan, Williams, & Anderson, 1992; Ollendick et al., 1989). Earlier reviews of this literature (e.g., Morris & Kratochwill, 1983; Ollendick & Francis, 1988; Silverman & Nelles, 1990) indicated that loss of support, loud noises, and unfamiliar people predominate in infancy; imaginary creatures, small animals, and the dark predominate in the middle childhood years; and achievement/performance, social-evaluation, and bodily injury predominate in early and late adolescence.

Longitudinal investigations corroborate these patterns. For instance, McGee et al. (1992), in a study of community children (N = 925) assessed at age 11 and again at age 15 (using structured diagnostic interview and parent ratings), found that the content of children's fears changed over time. At age 11, children's fears were likely to be of the dark, heights, or animals; at age 15, the fears were likely to be of social and agoraphobic situations.

Although research using clinic samples of children with anxiety disorders is sparse (e.g., Last, Perrin, Hersen, & Kazdin, 1992; Strauss & Last, 1993), extant findings suggest similar developmental patterns in the content of childrens' fears. For instance, children with a primary diagnosis of social phobia (SOP; social-evaluation/performance fears) tend to be older than children with a primary diagnosis of separation anxiety disorder (SAD) or SP (animals, dark) (see Section 5.14.2).

5.14.1.2 Gender Variations

Research on gender variations using clinic samples has been conducted primarily with respect to prevalence rates (see Section 5.14.5). Research on gender variations in children's fears using nonclinic populations, and using self-, parent-, teacher-, and peer-ratings, shows that girls report more fears, and obtain higher fear ratings from others, than do boys (both frequency and intensity) (e.g., Croake, 1969; Ollendick, 1983; Ollendick & King, 1994; Ollendick, Yang, Dong, Xia, & Lin, 1995; Ollendick, Yule, & Ollier, 1991; Silverman &

Nelles, 1988b). One common explanation is that gender role expectations or attributions may be operating. That is, it is more acceptable for girls than for boys to act "feminine," which includes admitting to fears or behaving in a fearful manner (Maccoby, 1980). Consistent with this notion is the finding that children of both genders tend to ascribe more fear to girls than to boys (Ollendick et al., 1995; Silverman & Nelles, 1988b).

Although a positive relation between "femininity" and a negative relation between "masculinity" (as measured by self-report measures) and fear/anxiety have been found in adult populations (Carey, Dusek, & Spector, 1988; Dillon, Wolf, & Katz, 1988), these hypotheses have not been investigated directly in children. However, preliminary findings from a study on gender and children's fears (Ginsburg & Silverman, 1997) suggest that self-ratings of fear may indeed be associated with gender role orientation. Based on a clinic sample of children ($N = 92$; mean age = 10.3 years) diagnosed with a primary *DSM-III-R* anxiety disorder, a significant negative correlation ($r = -0.21$; $p < 0.05$) was found between children's total scores on the FSSC-R and self-ratings of masculinity on the Children's Sex Role Inventory (Boldizar, 1991).

5.14.1.3 Race and Cultural Variations

Studies of children's fears using nonclinic samples suggest that fears (as measured by child self-rated fear surveys) may be more frequent and intense in American minority groups, such as African-Americans, than in Caucasians (Lapouse & Monk, 1959; Nalven, 1970; Neal & Turner, 1991). Reviews of these studies also suggest that level of fearfulness as well as the presence of specific fears may vary by culture (see Fonesca, Yule & Erol, 1994). For example, a study by Ollendick, Yang, King, Dong, and Akande (1996) examined fears (using the FSSC-R) of 1200 children, (aged 7–17 years), from the US, Australia, China, and Nigeria (300 children from each country), and found several differences in number, level, and content, as well as differences in developmental and gender patterns across countries. One finding, for instance, was that Nigerian children reported more and higher levels of fear compared to their American, Australian, or Chinese counterparts, who did not differ from each other. Moreover, girls and boys in Nigeria reported similar levels of fear; girls in each of the other countries reported higher levels than boys. Finally, the Nigerian children were more likely to report intense fears associated with physical danger (e.g., snakes, guns, getting shock from electricity); the American and Australian children reported more intense fears of personal safety (e.g., burglars, getting lost). In explaining these cultural variations in fears, Ollendick et al. (1996) point to cultural differences in socialization practices. That is, countries such as Nigeria tend to emphasize socialization practices such as inhibition, compliance, and obedience (and thus children with more fear), and countries such as the US and Australia do not have this emphasis.

Despite these cultural variations, several studies have found similarities in the types of objects and situations feared by children across cultures. For example, in comparing the top 10 fears endorsed on the FSSC-R by children from five different countries (Portugal, UK, Turkey, Australia, and US), seven of the fears were the same across countries (Fonesca et al., 1994). These included: fears of being hit by a car or truck; not being able to breathe; bomb attacks; fire/being burned; burglars; falling from a height; and serious illness. Similarly, in the Ollendick et al. (1996) study cited above, the most common intense fears (i.e., the 10 fears rated "a lot" with the greatest frequency) across countries showed considerable overlap, and reflected fears of danger and/or death (e.g., not being able to breath, being hit by a car or truck, bombing attacks, failing from high places, death/dead people) and failure and/or criticism (e.g., failing a test, having parents argue, and getting poor grades).

Taken all together, the results from cross-cultural studies using nonclinic samples of children suggest that although certain types of fears appear to be culturally meaningful or specific, there also appear to be certain types of fears that are experienced uniformly by children across various cultures. Further research on the specific nature of the socialization practices (e.g., parenting practices) that influence the development of childhood fears across cultures awaits further systematic study.

In terms of racial/cultural variations using clinic samples of youth with anxiety disorders, findings, although sparse, suggest that youth with SP may be more alike than different. For instance, Last and Perrin (1993) compared the sociodemographic background, clinical characteristics, and life-time prevalence rates of *DSM-III-R* anxiety disorders (not only SP) of African-American ($N = 30$) and White children ($N = 139$) aged 5–17 years who presented to a childhood anxiety specialty clinic. Relevant to SP, Last and Perrin found that although the African-American children scored higher than the White children on the FSSC-R, the difference did not reach statistical significance.

Ginsburg and Silverman (1996) compared various characteristics of Hispanic ($N = 90$) and Caucasian children ($N = 143$) who presented to a childhood anxiety specialty clinic. Similar to the findings of Last and Perrin (1993), the children were more similar than different on the variables examined. One significant difference relevant to SP, however, was that the Hispanic parents rated their children as having more fears than did the parents of Caucasian children (using a parent version of the FSSC-R).

In sum, as far as we know, only two studies have examined systematically race and cultural variations of fears in clinic samples that included children with SP (Ginsburg & Silverman, 1996; Last & Perrin, 1993). Although both studies found more similarities than differences between the samples studied, further research is needed before firm conclusions are drawn.

5.14.2 ONSET AND STABILITY

Research has shown that the onset of many SPs occurs during childhood or adolescence (e.g., Ost, 1985, 1987; Ost & Hugdahl, 1983; D. V. Sheehan, K. E. Sheehan, & Minichiello, 1981; Thyer, Parrish, Curtis, Nesse, & Cameron, 1985), and that some SPs are stable over time. For example, one of the most extensive studies on the onset of SP, based on the retrospective reports of adult patients with SP ($N = 370$), reported that the average age of onset for animal phobia was seven, age nine for blood phobia, and age 12 for dental phobia (Ost, 1987).

Other studies, using retrospective reports of adult patients with SP have found similar patterns with respect to age of onset. For instance, Marks and Gelder (1966) found that the onset of phobias of darkness, insects, and blood-injury began before age seven; the onset of animal phobias was somewhat earlier, age 4.4 years. Liddell and Lyons (1978) found that the age of onset for blood phobia was 8.8 years, 10.8 years for dental phobia, and 11.9 years for thunderstorm phobias.

Another way to glean information about the onset and stability of SP in children is to examine the ages in which children present for treatment for SP and to assess the disorder's duration. Last et al. (1992) examined sociodemographic and clinical characteristics of youth ($N = 188$; aged 6–18 years) referred to a child anxiety specialty clinic and reported on developmental variations in primary *DSM-III-R* anxiety diagnoses. The average age at intake for children with a primary diagnosis of SOP ($N = 61$) was found to be 14.4 years, 10.3 years for SAD ($N = 84$), and 12.1 years for SP ($N = 80$). With respect to age of onset, the ages were 11.3 years for SOP, 7.5 years for SAD, and 8.4 years for SP.

Strauss and Last (1993), in a comparison of clinical characteristics of children who presented to a childhood anxiety clinic with primary diagnoses of either SP or SOP (aged 4–17 years), found that of the children with SP (N = 38; mean age = 11.1 years) the mean age of onset was 7.8 years and the average duration of the children's SP was 3.3 years.

In examining the average age at intake for children who presented to our research clinic, the Child Anxiety and Phobia Program at Florida International University, Miami, it was found also that the average age of the children ($N = 340$; aged 5–18 years) with primary *DSM-III-R* anxiety diagnoses varied. For instance, the average age of children with SAD ($n = 51$) was 8.7 years, 11.7 years for SOP ($n = 42$), and 9.9 years for SP ($n = 143$).

Finally, results obtained from longitudinal studies are yet another way to glean information about onset and stability of SP in children. Perhaps the most widely cited study is that of Agras, Chapin, and Oliveau (1972). They followed a community sample of 30 untreated phobic individuals (10 children under the age of 20 years and 20 adults) over a five-year period. After five years, 100% of the children were viewed as "improved" compared to 43% of the adults. Although the conclusion drawn by Agras et al. was that many phobic conditions improve without treatment, particularly in children, a reinterpretation of these data (Ollendick, 1979) revealed that the improved children were not symptom-free, and most continued to exhibit symptoms of sufficient intensity to be rated between "no disability" and "maximum disability" at the follow-up assessment. Ollendick's reinterpretation thus suggested that some types of phobias persist over time for a proportion of youngsters.

Another study conducted by Milne et al. (1995) examined the frequency of clinical phobias (SP, SOP, and agoraphobia (AG) combined) and subclinical fears in a community sample of youth over a one-year period as part of a large, two-stage epidemiological study on adolescent depression. In the first stage of the study (screening stage), a depressive symptom questionnaire was administered to a large community sample ($N = 3283$; 80% were White and the majority were 7th-graders). In the second stage (diagnostic stage), a selected sample of youth and their mothers ($N = 487$) were assessed with a structured diagnostic interview. These stages were repeated annually for up to three years, the number of children assessed at all three time periods was 112. Relevant here is the finding that of the 112 youth, 11% (with any type of phobia; $n = 12$) continued to meet diagnosis for that same type of phobia one year later.

5.14.3 DIAGNOSIS

A summary of the criteria for an SP diagnosis using the *DSM-IV* (APA, 1994) and *ICD-10* (World Health Organization, 1992) systems are presented in Table 1. In both systems, a diagnosis of SP is assigned when children display a persistent, recurrent, and/or excessive fear toward an object or event. Exposure to the phobic stimulus generally provokes an immediate anxiety reaction, often manifested in children as crying, having tantrums, freezing, or clinging. Generally, the phobic situation is avoided or experienced with severe distress. A key factor in assigning a diagnosis of SP is that the symptoms must impair functioning significantly.

Differences in the *ICD-10* and *DSM-IV* pertain to their views about the classification of the phobia as an adult or child disorder (based on whether the fear is developmentally age-appropriate), about the persistence of symptoms, and the classification of phobia subtypes. Specifically, according to *ICD-10*, phobias may be classified as either of one of two disorders, "phobic anxiety disorder of childhood" (under the broader category, "Emotional Disorders with Onset Specific to Childhood") or "phobic anxiety disorder" (under the broader category, "Neurotic, Stress-related, and Somatoform Disorders"), generally used for adults. The criteria for the childhood-onset disorder requires that the fears be age-appropriate but excessive and impairing. In cases in which fears are not age-specific, the adult disorder is assigned to that child as a diagnosis. In contrast, *DSM-IV* has only one classification for phobias, and fears need not be age-appropriate to be assigned the diagnosis. For *ICD-10*, duration is

Table 1 Diagnostic criteria for specific phobias in children.

DSM-IV

A. A marked, persistent fear that is excessive or unreasonable, prompted by the presence or anticipation of an object or situation (e.g., flying, heights, animals)
B. Exposure to the feared object or situation usually provokes an immediate anxiety response. In children this may be expressed by crying, tantrums, freezing, or clinging
C. A recognition that the fear is excessive or unreasonable (this feature may be absent in children)
D. The feared object or situation(s) is avoided or endured with intense anxiety or distress
E. The avoidance or distress toward the feared object or situation significantly interferes with the person's normal routine, occupational (or academic) functioning, or social activities or relationships, or causes marked distress
F. Fear is present for at least six months for individuals under age 18 years
G. The individual does not meet criteria for another mental disorder that better accounts for their anxiety, panic attacks, or phobic avoidance associated with the specific object or situation (e.g., obsessive compulsive disorder, separation anxiety disorder)

ICD–10 (includes both child and adult descriptions)

A. Phobic anxiety disorders. Disorders in which anxiety is evoked only, or predominantly, in well-defined situations that are not currently dangerous. Consequently, these situations are avoided or endured with dread. The patient's concern may be focused on individual symptoms like palpitations or feeling faint and is often associated with fears of dying, losing control, or going mad. Contemplating entry to the phobic situation usually generates anticipatory anxiety
B. Specific (isolated) phobias. Phobias that are restricted to highly specific situations such as proximity to particular animals, heights, thunder, darkness, flying, closed spaces, etc. Types of specific phobias are classified as: acrophobia, animal phobia, claustrophobia, simple phobia
C. Phobic anxiety disorder specific to childhood. Fears displayed during childhood, that arise in a majority of children, but that are abnormal in degree. Fears displayed in childhood that are not a normal part of psychosocial development (e.g., agoraphobia) are coded under the adult categories
D. Excludes generalized anxiety disorder and when associated with conduct disorders

not part of the diagnostic criteria; for *DSM-IV*, the children's symptoms must be continuous for six months to receive a diagnosis. Finally, *ICD-10* childhood onset does not specify subtypes of SP; *ICD-10* adult-onset phobia subtypes include: acrophobia, animal phobia, claustrophobia, simple phobia. The subtypes of *DSM-IV* are: animal (e.g., cats, dogs, insects); natural environment (e.g., storms, heights, water); blood-injection-injury (e.g., seeing blood, needles); situational (e.g., public transportation, elevators, flying); and other (e.g., loud noises, costume characters).

5.14.3.1 Differential Diagnosis

A diagnosis of SP should only be given once other anxiety conditions have been ruled out. For example, according to the *DSM*, a diagnosis of SP is assigned only when the fear is not restricted to situations that involve separation (as in SAD), social-evaluation and embarrassment (as in SOP), dirt/contamination (as in obsessive compulsive disorder, OCD), or fears of having a panic attack and/or being unable to escape (as in panic with or without AG). It is also essential that the fear not be a part of a larger reaction to a traumatic event, as in post-traumatic stress disorder, or a more pervasive pattern of anxiety, as in generalized anxiety disorder (GAD).

Finally, although children who refuse to attend school are often labeled as having a "school phobia," research has revealed that these children refuse school for a myriad of reasons (Bernstein & Garfinkel, 1986; Burke & Silverman, 1987; Kearney & Silverman, 1997) which may or may not be related to having SP. For instance, a child may refuse to attend school because of fears of speaking in class (SOP), being away from a parent (SAD), or hearing the bell ring (SP, situational subtype). Thus, to derive a differential diagnosis for children who present with school refusal, it is important to carefully assess the specific reasons for the school refusal.

5.14.3.2 Comorbidity

Clinic and community studies indicate that up to one-half of all children present with more than one comorbid disorder (see Caron & Rutter, 1991 for a review). Several studies examining the comorbid patterns among samples of clinic-referred children with anxiety disorders have been conducted (e.g., Last, Strauss, & Francis, 1987; Last et al., 1992; Strauss & Last, 1993). Last et al. (1987) examined the comorbid *DSM-III* diagnoses of a sample of 73 children (aged 5–18 years) with primary diagnoses of SAD ($n = 24$), overanxious disorder (OAD; $n = 11$), SP ($n = 11$), and major depression ($n = 11$). Findings with respect to SP indicated that 64% of the children in the SP group had a comorbid diagnosis. The most common comorbid anxiety disorder was SAD (39%).

In a subsequent study, Last et al. (1992) examined comorbid lifetime history diagnoses in children with anxiety disorders ($N = 188$; aged 5–18 years). Relevant to SP were the findings that 60 of the 80 children (75%) with a primary diagnosis of SP had a lifetime history of any anxiety diagnosis; 32.5% had a history of any depressive disorder; and 22.5% had a history of any disruptive disorder. The most common additional anxiety disorder was again SAD ($n = 31$; 38.8%).

Hammond-Laurence and Silverman (1997) examined current rates of comorbid diagnoses in a large sample of children referred to an anxiety specialty clinic ($n = 356$; aged 6–17 years. With respect to SP, the findings indicated that this was the most common diagnosis of the sample and, typically, children with a primary diagnosis of SP met criteria for a secondary diagnosis of another SP (29%) or SAD (18%). Also of interest is the finding that children with only one anxiety disorder tended to be rated lower (on average) in clinical severity relative to children with multiple disorders, indicating that there is "clinical significance" to having multiple comorbid disorders.

Although the high comorbid rates reported in the studies just cited could be due in part to the Berkson effects, that is, both the Last et al. (1987, 1992) and the Hammond-Laurence and Silverman (1997) studies were conducted at anxiety specialty clinics that attract the most severely anxious youth, these findings are in accord with the growing body of literature concerned with comorbidity (Caron & Rutter, 1991). However, a great deal more work is needed to understand the meaning and implications of comorbidity, not only in terms of clinical presentation, but also in terms of prognosis and treatment.

5.14.4 ETIOLOGY

5.14.4.1 Biological

Evidence for the role of biological factors is based largely on findings from family aggregate and twin studies (e.g., Burglass, Clarke, Henderson, Kreitman, & Presley, 1977; Davey, Forster, & Mayhew, 1993; Fyer et al., 1990; Fyer, Mannuzza, Chapman, Martin, & Klein, 1995; Kendler, Neale, Kessler, Heath, & Eaves, 1992; Last, Hersen, Kazdin, Orvaschel, & Perrin, 1991; Moran & Andrews, 1985; Noyes et al., 1986; Reich & Yates, 1988; Solyom, Beck, Solyom, & Hugel, 1974; Torgersen, 1979). Not all of these studies focused exclusively on SP, but examined various types of phobic and anxiety disorders. Overall, however, these studies provide support for a positive familial contribution to these disorders.

A representative study that focused on SP was conducted by Fyer et al. (1990). In this study, the probands of adults diagnosed with SP (*N* = 49) were assessed, including all their first-degree relatives, using the Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978). First-degree relatives of a normal proband group (*N* = 119) served as the control group. The results indicated that relatives of individuals with SP evidenced a higher rate of SP themselves (31%) compared with relatives of those in the comparison group (11%). In addition, 15% of the children whose parents had SP, compared to 8% of children whose parents did not have SP, evidenced SP.

Another study by the same research group (Fyer et al., 1995) compared the familial aggregation of three different types of phobic disorders: SP (*N* = 15), SOP (*N* = 39), and panic with AG (*N* = 49). All participants were of European descent, with one living first-degree relative, and were recruited from ongoing studies that were being conducted at two different anxiety disorders research clinics. None of the participants who comprised each of the three phobic disorder groups had comorbid diagnoses (present or lifetime). The control participants, who were recruited from a randomly selected patient acquaintance list, were 77 "not ill" individuals, that is, no past or current psychiatric diagnoses. *DSM-III-R* diagnoses were assessed using a combination of a direct interview (i.e., SADS-Lifetime Anxiety Version) and family informants' reports.

The results indicated that relatives of individuals in the SP group had significantly higher rates of SP (31%) than the relatives of individuals in the control group (9%). Interestingly, the rates of SP in the relatives of individuals with panic/AG (10%) and SOP (13%) did not differ significantly from the rates found in the relatives of individuals in the control group (9%). In interpreting these results, Fyer et al. (1995) suggested that there may be an "existence of separable, etiologically discrete syndromes within the group of cases identified by each of the three *DSM-III-R* criteria sets" (p. 572). However, the authors caution that this notion may apply to "pure" diagnostic cases (i.e., those with no present or life-time comorbid diagnoses). Also not clear is whether it applies to each subtype of SP (e.g., if relatives of blood phobics were more at risk for blood phobias than for dog phobias) as this issue was not examined due to limited sample sizes. In addition, although the findings provide evidence for some type of familial risk for SP, what is not clear is whether this familial risk is due to shared genes, common family environmental factors, or an interaction of the two (Foley & Hay, 1992; Silverman, Cerny, & Nelles, 1988).

Additional evidence of a biological contribution comes from twin studies (e.g., Abe, Oda, Ikenaga, & Yamada, 1993; Kendler et al., 1992; Slater & Shields, 1969; Stevenson, Batten, & Cherner, 1992; Torgersen, 1979; Young, Fenton, & Lader, 1971). For example, in one of the largest studies examining genetic and common familial environmental influences in the etiology of phobic disorders (AG, SOP, and SP), Kendler et al. administered diagnostic and clinical interviews to 2163 adult female twins recruited from a population-based twin registry. Findings relevant here indicated that concordance rates of animal phobia for monozygotic and dizygotic twins were 25.9% and 11.0%, respectively. Concordance rates for situational phobia for monozygotic and dizygotic twins were 22.2% and 23.7%, respectively. According to Kendler et al., such findings provide support for the contribution of genetic factors in the etiology of SP, with a higher contribution of familial environmental factors operating for situational phobias.

Another avenue for investigating biological contributions to SP has been in the area of behavioral inhibition. Behavioral inhibition (BI) refers to the temperament of approximately 10–20% of Caucasian infants who are predisposed to being irritable, shy, and fearful as toddlers, and cautious, quiet, and introverted as school-aged children (e.g., Biederman et al., 1990, 1993a, 1993b; Hirshfeld et al., 1992; Kagan, Reznick, & Gibbons, 1989; Kagan, Reznick, & Snidman, 1987). Although studies generally support a positive association between anxiety disorders and BI in children, it is premature to conclude that BI is linked uniquely with SP, or with any other specific anxiety disorder.

With this caveat in mind, emerging evidence from this line of research suggests that BI in infancy may be a risk factor for phobic disorders (e.g., Biederman et al., 1990, 1993a, 1993b). For example, a study conducted by Biederman et al. (1990) used a structured interview (DICA-parent version) to examine the prevalence of *DSM-III-R* internalizing disorders (i.e., major depression, SAD, OAD, avoidant disorder [AVD], phobic disorders, and OCD) as well as externalizing disorders (i.e., oppositional defiant, conduct, attention deficit disorder, encopresis, enuresis) in three different cohorts of children. The first cohort, examined cross-sectionally, was the at-risk group and comprised offspring of parents with psychiatric diagnoses. Children in this cohort were classified as either inhibited ($N = 18$; mean age = 5.9 years) or uninhibited ($N = 12$; mean age = 4.9 years). The second cohort (Kagan's original cohort; Kagan, Reznick, & Snidman, 1987, 1988) was an epidemiologically derived sample of children who, at age 21 months, had been classified as either inhibited ($N = 22$) or uninhibited ($N = 19$). The mean age of the children at the time of the reassessment was 8 years. The third cohort of children had no medical or psychiatric disorders ($N = 20$; mean age = 7.8 years) and was obtained from primary pediatric care referrals.

Most relevant here are the findings that were found with the children in Kagan's original cohort. Specifically, the findings indicated that the inhibited compared with the uninhibited children had significantly higher rates of phobic disorders (31.8% vs. 5.3%, respectively). Inhibited compared with uninhibited children also had higher rates of OAD, SAD, and AVD, but this finding was not statistically significant. In exploratory analyses of the specific fears of the children who met criteria for a phobic disorder ($n = 9$), the results indicated that the average number of fears per child was 3.4, and that the most common fears were: standing up and speaking in front of class ($n = 5$); animals or bugs ($n = 5$); strangers ($n = 4$); the dark ($n = 4$); being called on in class ($n = 3$); crowds ($n = 3$); elevators ($n = 2$); and physicians ($n = 2$).

In a review of the research literature on BI and anxiety disorders, Turner, Beidel, and Wolff (1996) concluded that children with stable BI have higher rates of anxiety disorders (any type) and phobias compared with uninhibited children. With respect to phobias, BI appears to be associated most closely with those phobias that are social or social-evaluative in nature. Turner et al. also pointed out that although the research suggests that BI is neither necessary nor sufficient for developing an anxiety/phobic disorder, its presence may serve to increase children's vulnerability to anxiety disorders, including SP.

5.14.4.2 Psychosocial Factors

The emphasis that may be placed on specific psychosocial factors is likely to be influenced in part by the theoretical model or orientation to which the researcher or practitioner ascribes (e.g., psychoanalytic, behavioral, cognitive, familial). These models are summarized briefly below.

5.14.4.2.1 Psychoanalytic

According to the psychoanalytic perspective (Freud, 1909/1955), phobias develop in response to unconscious forbidden sexual or aggressive impulses. The anxiety experienced by these impulses are "defended" against via displacement of these feelings on to less threatening objects or situations. Hence, in Freud's famous case of Little Hans, Hans' phobia of horses was attributed to his attempt to defend against or avoid anxiety aroused by his sexual desire for his mother and his wish to do away with his father, the competitor. The child defended against the anxiety of these impulses by displacing his feelings on to an external object that can be avoided (i.e., horses). It has been difficult to verify empirically the psychoanalytic conceptualization of SP because of the unconscious nature of the main, hypothesized processes, namely, displacement. Moreover, subsequent analysis of this case by Wolpe and Rachman (1960) revealed no direct evidence for Hans' wish to sleep with his mother, for his hatred or fear of his father, nor for the supposed relation between horses and Hans' father.

5.14.4.2.2 Behavioral

Behavioral perspectives emphasize the role of conditioning (classical, operant, and vicarious) in the acquisition of phobias. For instance, case reports, such as Little Peter (Jones, 1924a; 1924b) and Little Albert (Watson & Rayner, 1920), demonstrated how a child could acquire a phobia of a previously neutral stimulus (e.g., a rat) by contiguous pairing with an aversive event. Empirical and case reports have supported both direct (classical conditioning) and indirect (vicarious exposure) conditioning models (e.g., Liddell & Lyons, 1978; Merckelbach, De Ruiter, Van De Hout, & Hoekstra, 1989).

Subsequent research has extended initial, conditioning theory to "neoconditioning" theory, reflected by the writings of Rescorla (1988) and Davey (1992). In Rescorla's and Davey's reformulation of conditioning, the emphasis is not on contiguous pairing of stimuli but on one's expectancy that the conditioned stimulus predicts the unconditioned stimulus and by one's evaluation of the unconditioned stimulus. According to this reformulation, learning that a stimulus predicts another occurs separately from learning that the predicted stimulus is aversive. For example, by often playing near a neighbor's house in which a big dog sits in the yard, a child may learn that the house is associated with the presence of a big dog. If the child is later bitten by a dog in some other location, the child may come to fear the neighbor's house because it reliably predicts a stimulus (a dog) that has acquired aversive properties. Reiss (1991), similarly, delineated a neoconditioning theory, one that also emphasizes a cognitive expectancy account that involves certain individual personality differences, such as anxiety sensitivity.

Also representing an important extension of conditioning theory was Mowrer's (1939) two-factor model which postulated Pavlovian conditioning in the initial acquisition of fear, and operant conditioning in the maintenance of fear in that fear serves as an acquired source of motivation or drive, (i.e., behaviors that reduced fear are reinforced). The adequacy of Mowrer's two-factor model in explaining the persistence of phobic fear and avoidant behavior has been questioned, however, because many individuals with phobias can confront the phobic stimulus without either covert avoidance or a subsequent aversive unconditioned stimulus (Menzies & Clarke, 1995). That is, according to Mowrer, this should lead to reductions in fear and avoidant behavior, but this does not always occur (Clarke & Jackson, 1983). Modified conditioning explanations consequently have been developed to account for this, such as the partial irreversibility of fear account (Solomon & Wynne, 1954), the preparedness account (Seligman, 1970, 1971), the incubation account (Eysenck, 1979), the safety signal account (Rachman, 1983), and the serial conditioned stimulus account (Stampfl, 1991).

Yet another way to conceptualize phobia acquisition (or reacquisition) is the notion of dishabituation of formerly mastered fears. More specifically, this is the notion that fears are not unlearned but are tempered or assuaged via habituation or extinction in certain contexts. Bouton (1991) reviewed evidence in support of this view, suggesting that extinction of fear responses do not involve unlearning of previously learned associations; rather, it involves learning to discriminate contexts in which the conditioned stimulus–unconditioned stimulus relationship exists from contexts in which the relationship does not exist. Hence, from this perspective, reinstatement of children's fears can occur when children are reexposed to fearful stimuli in situations that are not associated with safety.

Rachman (1977) espoused the importance of additional pathways in "indirect" fear acquisition, namely, vicarious exposure and the transmission of information or instruction. Support for these pathways has been provided in the subclinical fears of adults (e.g., Hekmat, 1987; Murray & Foote, 1979; Ost, 1985; Rimm, Janda, Lancaster, Nahl, & Dittmar, 1977), and in the fears of nonclinic referred children (Milgrom, Mancle, King, & Weinstein, 1995; Ollendick, King & Hamilton, 1991).

Taken all together, empirical support for the various conditioning reformulations and extensions have been uneven across laboratories, samples, disorders, and so on. This unevenness helped, in part, to spur the "cognitive revolution" that occurred in behavioral psychology in the 1970s. This perspective is discussed next.

5.14.4.2.3 Cognitive

Maladaptive cognitions and cognitive processes are believed to play an important role in the etiology and/or maintenance of SP. It is unclear, however, whether such cognitive activity is the cause or consequence of the fear response. Also unclear is how cognitions and/or cognitive processes vary with development. In contrast to the research literature on cognitive explanations of SP in adults, literature on this issue in children is sparse. Moreover, the extant studies are based on either nonclinic samples of children with different types of fears, or on clinic samples of children with different types of anxiety disorders. Nevertheless, these studies provide some useful information which may shed light on the role of cognitions and cognitive processes in children with SP.

In terms of cognitions, Kendall and colleagues (e.g., Kendall & Chansky, 1991) have suggested a heuristic distinction between cognitive deficiencies (i.e., a lack of cognitive activity such as problem solving, planning, or perspective taking) and cognitive distortions (i.e., cognitive activity that is characterized by misperceptions, exaggerations, or overattending to environmental threat). Children with excessive fear and anxiety are hypothesized to present with the latter. In support of this hypothesis, early research on the cognitive activity of highly anxious children indicated that these children are more likely than their nonanxious counterparts to engage in cognitive distortions, such as thoughts that focus on negative evaluations or unfavorable social comparisons (e.g., Francis, 1988; Prins, 1985; 1986; Zatz & Chassin, 1985).

Prins (1986), for example, examined children's self-speech and self-regulation during a fear-provoking task. Forty-four children (aged 8–12 years) with varying levels of fear of water were asked to perform three tasks in a pool that provoked differential levels of fear (e.g., jumping or diving from a low board, diving from a high board). The children were classified into three groups (high, moderate, and low anxious) based on their performance during a regular swimming lesson at school, observed by the researchers. Children's self-statements (positive, neutral, negative) were assessed via interviews immediately following each task. Relevant here were the findings that the children in the high anxious group engaged in significantly more negative self-statements (e.g., "I'll fall hard," "It will go wrong," "Last time I fell on my belly,") relative to the children in the moderate and low anxious groups. Interestingly, however, no differences were observed among the groups in the frequency of positive or neutral self-statements.

In a study using adolescents recruited from high schools, King, Mietz, Tinney, and Ollendick (1995) compared the cognitions of adolescents who were low and high in test anxiety. Classification of low (*N* = 25; mean age = 15.6 years) and high (*N* = 22; mean age = 15.75 years) test anxiety was based on the adolescents' scores (i.e., the bottom and top 5%) on the Test Anxiety Scale for Children (TASC; Sarason, Davidson, Lighthall, Waite, & Ruebush, 1960). The two groups were compared on psychiatric diagnoses, levels of fear, anxiety, depression, and cognitions. Cognitions were assessed after a brief math and language test using the Children's Cognitive Assessment Questionnaire (CCAQ; Zatz & Chassin, 1983, 1985). The CCAQ has 50 statements about different types of thoughts: on-task, off-task, positive and negative self-evaluations, and coping self-statements. Findings with respect to diagnoses indicated that of the high test anxious youth that were interviewed (*n* = 18), 61% had an anxiety or phobic disorder (four youth had SP) compared to 2% of children in the low anxious group. With respect to cognitions, the adolescents in the high test anxiety group reported more off-task thoughts (e.g., "I wish this were over"), more negative self-evaluations (e.g., "I'm doing poorly on this"), more coping thoughts (e.g., "try to relax"), and fewer positive self-evaluations (e.g., "I do well on tests like this") than the adolescents in the low test anxious group. According to King et al., these results are consistent with the notion that nonnegative thinking may be related more strongly to adjustment than positive thinking (i.e., Kendall's notion of the "power of non-negative thinking"). Clinically, the implications are that it might be important to teach children with high test anxiety to control their off-task and negative self-talk rather than teaching the development of coping self-statements.

There is also a growing body of research on the factors that influence the thinking of anxious children. Some of these studies have included subsamples of youth with SP (Barrett, Rapee, Dadds, & Ryan, 1996), while some have not specified the specific types of anxiety disorders comprising the samples (e.g., Chorpita, Albano, & Barlow, 1996). Some of the factors that have been examined include: cognitive interpretive style (Barrett et al. 1996; Chorpita et al., 1996); causal attribution (Bell-Dolan & Wessler, 1994); and attentional bias (e.g., Vasey, Daleiden, Williams, & Brown, 1995). For example, in Barrett et al.'s study on children's cognitive interpretive style, children (aged 7–14 years) with anxiety disorders (*N* = 152; 27 had SP) were presented with several ambiguous situations and were asked to provide interpretations of the situations and to problem-solve a plan of action. One-half of the situations were social in nature (e.g., "You are going to school and a group of children are following you ... ") and the other half were physical (e.g., "On the way to school you feel funny in your tummy ... "). The comparison groups were nonclinic-referred children (*n* = 26) and clinic-referred children with *DSM-III-R* diagnoses of Oppositional Defiant Disorder (ODD; *n* = 27). The results indicated that the children with anxiety disorders perceived more threat in the ambiguous situations than the nonclinic children, but less threat relative to children with ODD. In addition, relative to both comparison groups, the children with anxiety disorders generated more avoidant plans as solutions to these situations. A closer examination of the responses of children with different primary anxiety diagnoses indicated that children with SP and OAD gave more threat interpretations to the physical situations than children with SAD. Moreover, children with SP gave more avoidant solutions to physical situations than children with any other type of anxiety disorder.

In terms of attentional bias, Martin, Horder, and Jones (1992) compared the response time for naming the colors of written words using a modified Stroop task of nonclinical school children (aged 6–13 years) with and without fears of spiders. Fearfulness was based on children's affirmative or negative responses to both of two questions: (i) whether the child liked spiders and (ii) whether the child would pick up a spider. All children completed a Stroop task that included spider-related and neutral words. The children with fears of spiders were found to be slower than the children without fears of spiders in their naming the color of spider-related words (e.g., web, crawl, hairy), supporting the notion of attentional bias in fearful children. Vasey et al. (1995) found similar results when they examined modified Stroop test performance using a sample of children (aged 9–14 years) with and without anxiety disorders ($N = 12$ in each group), supporting the hypothesis that children with anxiety disorders exhibit an attentional bias toward emotionally threatening stimuli. Vasey et al. further discuss how anxious children's narrowing of attention (i.e., hyperattention) may increase a child's focus on danger and threat stimuli, increase the encoding of threatening material, and thus maintain or increase levels of fear and anxiety.

In sum, empirical support is beginning to accumulate for the role of cognitions and certain cognitive processes in the etiology and/or maintenance of anxiety disorders. However, few studies have focused exclusively on the role of cognitions and cognitive processes in clinic samples of children diagnosed specifically with SP. This issue thus awaits further investigation.

5.14.4.2.4 Family

Familial contributions are also believed to play an important role in the development of SP. As noted in section 5.14.4.1, considerable evidence has documented that anxiety/fear "run in families." Specifically, findings from top-down studies generally reveal that children whose parents have an anxiety disorder are at risk of developing an anxiety disorder themselves (e.g., Silverman, Cerny, Nelles, & Burke, 1988; Turner, Beidel, & Costello, 1987; Weissman, Leckman, Merikangas, Gammon, & Prusoff, 1984). However, the specific mechanisms of transmission remain unclear. Two processes, parental modeling and parental child management (e.g., use of rewards and punishments) of fearful/avoidant behavior, have received the most attention by researchers. It is noted, however, that most of the studies conducted have not used clinic samples of children with SP. Most have used clinic samples of children with different types of anxiety disorders or nonclinic samples of children with different types of fears.

In terms of parental modeling, Milgrom et al. (1995) examined parental modeling as part of a larger study on origins of childhood dental fears. Children ($N = 895$; aged 5–11 years) recruited from public schools during dental exams, and their mothers or female guardians, were interviewed and administered several questionnaires to assess direct conditioning, parental modeling, and control variables (e.g., socioeconomic status (SES)). Most relevant here are the findings that among the parental modeling variables, maternal level of dental fear and maternal oral health were significant predictors of dental fears in the children, even after controlling for gender, age, and other sociodemographic variables.

Although not containing children with SP, another study conducted by Muris, Steerneman, Merckelbach, and Meesters (1996) provided further evidence for an association between parental modeling, particularly by mothers, and levels of child fear. These authors made use of the notion of "social referencing" in interpreting their findings: that is, children's tendencies to "look to" their parents, particularly their mothers, for emotional information as a way to appraise the dangers of a situation (Muris et al., 1996).

In discussing the contribution of parental modeling to child fear and anxiety problems, Silverman et al. (1988) suggested that it is not parental fear *per se* that is critical, but the extent to which parental fear is associated with parental avoidant behavior. Capps, Sigman, Sena, Henker, and Whalen (1996) provided evidence for this notion in a study in which they compared 16 offspring (aged 8–14 years) of parents with AG with 16 offspring of nonpsychiatric parents who were matched on age, gender, SES, and ethnicity. No significant correlation was found between parents' and children's self-ratings of fearfulness. However, the number of situations avoided by parents with AG was correlated significantly with the children's anxiety symptom scores, assessed via a structured interview.

In addition to parental modeling, research suggests that certain types of parental child management approaches may be associated with child fear and anxiety problems (e.g., Bush, Melamed, Sheras, & Greenbaum, 1986; Zabin & Melamed, 1980). For example, in Zabin and Melamed (1980), parents completed a questionnaire in which they endorsed the child management approach (e.g., positive reinforcement, punishment) that they used most often to encourage their child to deal with various fearful situations (e.g., getting a haircut, going to the dentist). Parental scores on this questionnaire were correlated with several indices of child trait anxiety (based on child and parent ratings) and state anxiety (based on child, parent, observer, and physiological measures) during their hospitalization for a fearful pediatric procedure.

Although measures of parent discipline varied in the strength of their relation to each of the child anxiety measures, and at each assessment period, overall, the patterns of results revealed that parental disciplinary techniques were associated with measures of child anxiety. More specifically, children whose parents endorsed using positive reinforcement and modeling of nonfearful behavior displayed low levels of child anxious behaviors (based on observer, child, and physiological measures). In contrast, children whose parents endorsed using punishment, physical force, or reinforcement of dependency displayed high levels of anxious behaviors (based on observer, parent, child, and physiological measures). Research findings obtained via direct observations of parent–child interactions of clinic samples of children corroborate this link between parental modeling as well as certain types of parental child management approaches and children's fear/anxiety problems (Barrett et al., 1996; Chorpita et al., 1996; Dadds, Barrett, Rapee, & Ryan, 1996). As noted, however, these studies contain too few children with SP (or the numbers are unspecified) to draw firm conclusions about the role of the family and family processes in the development of this particular disorder in children.

5.14.5 EPIDEMIOLOGY

Estimates of SP in childhood vary depending on the methodology used. Some of these methodological differences include variations in the informant (child, parent, both), the assessment method (structured vs. unstructured interviews), the sample (clinic or community), the age and gender of the participants, and whether an impairment index was included as part of the definition. Despite these differences, epidemiological studies provide a clearer picture than ever before of the prevalence of SP.

Table 2 presents findings from community studies, which have estimated rates of SP as ranging between 2 and 9% (e.g., Anderson, Williams, McGee, & Silva, 1987; Bird et al., 1988; Costello et al., 1988; Fergusson, Harwood, & Lynskey, 1993; McGee et al., 1990). The rate of SP among children who present for treatment has been estimated as being approximately 7% of referrals at outpatient community mental health clinics (Graziano & DeGiovanni, 1979; Silverman & Kearney, 1992), and approximately 30–35% of referrals at outpatient child anxiety specialty clinics (e.g., Last et al., 1987, 1992).

5.14.5.1 Prevalence of Phobia Subtypes

Information on the prevalence of each of the subtypes of SP among children is based largely on studies of youth who present to child anxiety specialty clinics. For example, in Strauss and Last's (1993) study, described earlier, in which the clinical characteristics of children with SOP and SP were compared, the most common subtypes of phobias of the 38 children (mean age 11.1 years) with a primary diagnosis of SP were: darkness 29%, school 24%, dogs 16%, other animals 8%, heights 8%, insects 8%, elevators 5%, and 3% for swimming, needles, drains, taxidermy.

In the Ginsburg and Silverman (1996) study, also described earlier, the most common subtypes of phobias were the same for the Hispanic and Caucasian children, namely, darkness/sleeping alone and small animals (i.e., dogs and cats). Silverman and Kearney (1992), in their survey of practicing psychologists, found that the most common types of fears treated were those relating to separation from caregivers, school, social situations, tests, and the dark.

5.14.5.2 Sociodemographic Risk Factors

Information detailing sociodemographic risk factors for SP is sparse. In this section, findings from community- and clinic-based studies are summarized briefly. These studies have tended to focus on SES, race, and gender.

5.14.5.2.1 Socioeconomic status

Most of what is known about SES as a risk factor for SP is based on samples of children who present at anxiety disorders specialty clinics. For example, in the Strauss and Last (1993) study in which the sociodemographic and clinical characteristics of children with SOP and SP were compared, Hollinghead index was used to assess SES. Of the subsample of children with SP, 22% were classified as levels I (major professionals) and II (medium business, minor professional, technical), 59% were classified as levels III (skilled craftsmen, clerical, and sales workers) and IV (machine operators and semiskilled workers) and 19% were classified as level V (unskilled workers, menial service workers). Last et al. (1992), in their comparison of the sociodemographic and clinical characteristics of a large sample of children with anxiety disorders ($N = 188$), found that most of the children with SP ($n = 80$) came from middle- to upper-class families.

In another study, annual family income was obtained for a sample (ages 6–17 years; mean age 10.1 years) of Caucasian ($N = 143$) and Hispanic ($N = 99$) families of youth with anxiety disorders (Ginsburg & Silverman, 1996). Of the Caucasian families, 8.5% had incomes of $15 000 or less, 22.6% had incomes of $15 000–30 000, and 68.9% had incomes over $30 000. Among the Hispanics, 29.2% had incomes of $15 000 or less, 28.1% had incomes of $15 000–30 000, and 42.7% had incomes over $30 000.

Table 2 Prevalence of specific phobias in epidemiological studies.

Study	*N*	*Age*	*M:F ratio*	*Rate of SP*
Anderson et al. (1987)	792	11	1:1.7	2.4
McGee et al. (1990)	943	15	1:2.9	3.6
Bird et al. (1988)	777	4–16		2.6
Costello et al. (1988)	789	7–11	1:2.0	9.2
Fergusson et al. (1993)	961	15		5.1
Kashani et al. (1987)	150	14–16	G > B	4.7
Kashani and Orvaschel (1990)	210	8,12,17	1:6	3.3

Source: Anderson (1994) and Silverman and Ginsburg (1998).

5.14.5.2.2 Racial/ethnic variations

Rates of SP and other psychiatric disorders were assessed in a community sample of youth in Puerto Rico using a multistage assessment procedure consisting of the parent and teacher versions of the Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1983) at the first stage (for screening), and a structured diagnostic interview at the second stage (for diagnosing) (Bird et al., 1988). As can be seen from Table 2, prevalence rates for SP in Puerto Rican youth (2.6%) were similar to those found in Caucasian youth.

Similar rates of SP in samples of African-American and White children (Last & Perrin, 1993) and in samples of Hispanic and White children (Ginsburg & Silverman, 1996), obtained from child anxiety specialty clinics, have also been reported. Specifically, Last and Perrin (1993) found that SP was among the "top" two primary diagnoses in both of their groups, both at intake (26.7% for African-Americans and 18.0% for Whites) and for lifetime prevalence (50% for African-Americans and 40.3% for Whites). Ginsburg and Silverman (1996) found SP to be the top primary diagnosis at intake in both of their groups, with a rate of 38.4% for Hispanics and 47.6% for Whites.

5.14.5.2.3 Gender

With respect to gender, several epidemiological studies have found rates of SP to be higher in girls than boys (see Table 2). This is consistent with the studies on nonclinical fears. In contrast, studies examining rates of SP in clinic samples of children generally have found rates of SP to be equal for boys and girls (Ginsburg & Silverman, 1996; Last & Perrin, 1993).

5.14.6 ASSESSMENT

The most widely used methods for assessing children's cognitive/subjective, behavioral, and physiological response systems (Lang, 1977) are summarized in this section. Choosing the "best" assessment procedure depends largely on the specific goal or desired outcome (e.g., self-rating scales may be best for screening, interview schedules for diagnosing) (Silverman & Kurtines, 1996). A protypical approach to assessment involves eliciting information from multiple perspectives (child, parent, teacher) and examining each of the three response systems. It is noted, however, that manifestations of fear/anxiety measured by these three systems do not necessarily covary (i.e., desynchrony).

5.14.6.1 Cognitive/Subjective

The most commonly used strategies to assess the cognitive/subjective system include clinical interviews, self-report questionnaires, and self-monitoring procedures, although these strategies may also be used to assess the behavioral (e.g., "do you try as hard as you can to stay away from dogs?") and physiological response systems (e.g., "does your heart beat fast when you see a dog?").

Clinical interviews are characterized as either unstructured (or nonstandardized) or structured (or standardized) (Richardson, Dohrenwend, & Klein, 1965). In the unstructured interview, the specific questions and the sequence of the questions asked vary depending on the interviewees' responses and on the interviewers' subjective judgements and training. Structured interviews contain a set of questions that are asked of all respondents in the same sequence (see Silverman, 1991, 1994, for reviews). Because of problems with the reliability of diagnoses derived from unstructured interviews (Edelbrock & Costello, 1984), the use of structured and semistructured interview schedules has increased through the years. Of the structured interviews available (e.g., the Schedule for Affective Disorders and Schizophrenia in School-Age Children; Puig-Antich & Chambers, 1978, the Diagnostic Interview for

Children and Adolescents; Herjanic & Reich, 1982, the Diagnostic Interview Schedule for Children; Costello, Edelbrock, Dulcan, Kalas, & Klaric, 1984), only the Anxiety Disorders Interview Schedule for Children (ADIS-C/P; Silverman & Nelles, 1988a; Silverman & Albano, 1996) was designed specifically for use with children with SPs and other anxiety disorders. Its utility for diagnosing SPs in youth has been studied extensively (Rapee, Barrett, Dadds, & Evans, 1994; Silverman & Eisen, 1992; Silverman & Nelles, 1988a; Silverman & Rabian, 1995), and have yielded excellent reliability coefficients (Kappa coefficients ranging from 0.84 to 1.0, depending on the reliability paradigm used (i.e., interrater, test–retest).

To assess the presence of SP, the ADIS-C/P contains a list of objects/events (e.g., dark, dogs, needles) to which the child/parent is instructed to rate the child's degree of fear and avoidance using a Feelings Thermometer. The Feelings Thermometer is useful in that it simplifies the rating task for children and removes some of the variability attributed to language skills that occur when young children respond to questionnaires (Barrios, Hartmann, & Shigetomei, 1981). In addition to fear ratings, the ADIS-C/P provides for an assessment of degree of interference by obtaining such ratings from the child and parent alike, also using a modified Feelings Thermometer. Additional sections of the ADIS-C/P contain questions addressing onset, course, and etiology of each specific phobia.

Another frequently used method for assessing the cognitive/subjective system are self-rating scales. The most widely used scale for assessing fears in children is the Revised Fear Survey Schedule for Children (FSSC-R; Ollendick, 1983). This measure provides information on the number, severity, and types of fears that children experience in 80 different situations. Factor analysis has revealed five factors including: (i) fear of the unknown, (ii) fear of failure and criticism, (iii) fear of minor injury and small animals, (iv) fear of danger and death, and (v) medical fears (Ollendick, 1983).

Other self-rating scales have been developed to assess a broad range of children's fears, including the Louisville Fear Survey (Miller, Barrett, Hampe, & Noble, 1972) and the Children's Fear Survey Schedule (Ryall & Dietiker, 1979). In addition, self-rating scales have been developed to assess children's specific fears, such as dental procedures (Children's Fear Survey Schedule; Melamed & Lumley, 1988), darkness (Nighttime Coping Response Inventory and Nighttime Fear Inventory; Mooney, 1985), medical procedures/hospital (Fears Schedule; Bradlyn, 1982), snakes (Snake Attitude Measure; Kornhaber & Schroeder, 1975), and tests (Test Anxiety Scale for Children; Sarason et al., 1960).

Despite the ease in administration and scoring of children's self-rating scales, as well as their apparent face validity, their utility in providing differential diagnoses, particularly of SP, awaits further study. Last, Francis and Strauss (1989), used the FSSC-R to compare the fears of 111 children (aged 5–18 years; mean age not provided) who presented at a childhood anxiety clinic and who met *DSM-III-R* criteria for a range of anxiety disorders. Specifically, 44 children had a primary diagnosis of SAD, 33 had a primary diagnosis of OAD, and 34 had a primary diagnosis of either SOP or SP (combined together as a "phobic group," with the most common subtype being school-related phobias). No differences were found across these diagnostic groups in either their total FSSC-R scores or their factor scores. Interestingly, however, differences among the groups were observed with respect to the total number of intense fears endorsed (i.e., number of items that children rated "a lot"), with the phobic group endorsing the least. Comparisons of the frequency of certain individual FSSC-R items indicated that children in the phobic group were more likely to endorse the school item than children in the OAD group, but were not different from children in the SAD group. Also, less than one-half of the children in the phobic group endorsed "a lot" of fear on the school item, despite the primary reason for being classified in the phobic group was based on reports of school-related fears obtained during a structured interview.

In another study, Perrin and Last (1992) examined the FSSC-R as well as other self-report measures of anxiety using a sample of 213 boys (aged 5–17 years); 105 with primary diagnoses of anxiety disorders (22 with SP), 56 with primary diagnoses of Attention Deficit Hyperactivity Disorder (ADHD), and 49 with no psychiatric diagnoses. With respect to children's fears, there were no differences among the three groups on the total or five subscale scores of the FSSC-R. There were also no significant differences in the FSSC-R scores of the boys with anxiety disorders who were also school refusers with the scores of the boys with ADHD as well as the normal controls.

In summary, although self-rating scales such as the FSSC-R are used widely, questions remain about their discriminative ability between youth with SP and normal controls as well as among various diagnostic groups. However, there may be some utility in a qualitative analysis of the individual items endorsed.

Another way to assess children's cognitive/subjective systems is via self-monitoring procedures. Self-monitoring requires that children self-observe and systematically record the occurrence of their fearful thoughts and behaviors. Self-monitoring data also provide information about the antecedents and consequences of fearful reactions as well as the severity and frequency of these reactions. In the authors' work, children engage in self-monitoring via a "daily diary." This requires the children to keep a record of the situations in which fear/anxiety was experienced, whether they confronted or avoided the situation, accompanying cognitions, and a rating of fear.

A more structured procedure described by Beidel, Neal, and Lederer (1991) requires children to mark on a checklist whether certain events occurred and whether they experienced certain feelings. In a community sample of elementary school children involved in an investigation of test-anxiety, Beidel et al. (1991) examined the reliability of the children's self-monitoring, and also compared the frequency and severity of anxiety-producing events during a two-week period for a text-anxious ($n = 17$) and nontest-anxious ($n = 17$) subsample. Compliance was also evaluated. As Beidel et al. point out, assessing reliability for an event-orient assessment procedure is difficult as events are variable and fluctuating. Not surprisingly, therefore, the resulting reliability coefficient (based on an n of 13) was relatively modest and not significant ($r = 0.50$). As preliminary support for validity, however, the test-anxious children reported significantly more emotional distress and more negative behaviors (e.g., crying, somatic complaints) than the nontest-anxious children. Compliance was found to be mixed, with 56% of the test-anxious children completing the forms on 10 of the 14 days, and with the percentage of children completing the forms for all 14 days dropping to 31%.

Similar types of analyses of self-monitoring assessment data using clinic samples of children with SP need to be done. In addition, reactivity effects and whether self-monitoring data are sensitive in showing clinical change from pre- to post-treatment warrant investigation. Methods to increase children's compliance with and accuracy of self-monitoring should also be studied.

5.14.6.2 Behavioral

Behavioral observation procedures provide useful information about the frequency and severity of symptoms/behaviors and their antecedents and consequences. In working with children with SP, the types of symptoms/behaviors that might be identified/assessed may be classified as (i) verbal behavior, such as rate of speech, positive/negative self-references, verbal social skills, etc., and (ii) overt behavior, such as head/gaze aversions, head nods, posture, eye contact, etc. Although there are a number of ways to observe these behaviors, the most frequent ways are on the basis of discrete response occurrences (i.e., response rate or frequency) or the amount of time that the response occurs (i.e., response duration).

Several observational coding procedures have been developed for assessing fear and anxiety in children. These coding procedures were developed to record discrete child behaviors in specific anxiety-provoking settings, such as in dental, medical, or child–parent separation settings (e.g., Glennon & Weisz, 1978; Melamed & Siegel, 1975). Such behavior observation coding schemes can be adapted for use with children with SP. They can also be adapted for use in analogous situations, which might be more feasible for clinicians.

Unfortunately, however, the psychometric properties of behavioral observation procedures in analogous situations have been insufficiently studied. An exception is a study conducted by Hamilton and King (1991) who examined the temporal stability of an analogous observation procedure using 14 children (aged 2–11 years; mean age not provided) with an SP of dogs. The analogous procedure comprised a series of 14 performance tests. Each test required the child to engage in increasingly more difficult interactions with a dog. Two test administrations were conducted seven days apart, prior to treatment. High test–retest reliability was obtained ($r = 0.97$), with 10 of the 14 children obtaining identical approach scores and with the other four children obtaining increased approach scores, (i.e., they displayed less avoidant behavior from Time 1 to Time 2). These results provide support for the temporal stability of approach scores obtained on analogous observation procedures. However, because of the small sample employed in this study and the wide age range, replication of this study would be worthwhile. Additional questions worth examining in the future include the role of differential levels of initial fear, the specific instructions employed (e.g., high demand vs. low demand), and children's developmental level.

5.14.6.3 Physiological

The most common strategies used to assess the physiological system typically involve measuring children's heart rate, blood pressure, and electrodermal activity (e.g., finger or palm sweat; see King, Hamilton, & Ollendick, 1988). These measurements are usually taken before, during, and after child exposure to the feared object or event. There is a paucity of data on the utility of these measures using samples of children with anxiety disorders, including SP. This is likely due to difficulties involved in using these procedures, including children's frequent movements, children's fears of the test instrumentation (e.g., the electrodes may shock them), and the instruments' sensitivity to nonanxiety influences (e.g., lighting, temperature, noise, novelty). There are also difficulties involved in the interpretive process with children, particularly as they relate to developmental level. For example, in relation to tonic heart rate in children, both heart rate and heart rate variability decrease with age (Shinebourne, 1974). Normative data for psychophysiological measurement with children are also lacking (Venables, 1981).

Despite these difficulties, evidence does suggest that psychophysiological assessment may be a reliable strategy for the assessment of children's anxious symptoms (e.g., Beidel, 1991; Beidel, Fink, & Turner, 1996; Murphy, Alpert, Wiley, & Somes, 1988). Unfortunately, however, the utility of psychophysiological assessments in clinical outcome studies of SP remains to be demonstrated adequately. In a treatment outcome study of childhood SP (described below), the results pertaining to heart rate tended to be uneven, similar to what has been reported in single case-design studies (e.g., Van Hasselt, Hersen, Bellack, Rosenblum, & Lamparski, 1979).

5.14.7 TREATMENT

The research literature shows that the one procedure that is essential to include in a fear or anxiety treatment program, if it is to be successful, is "exposure" (i.e., having the child confront or approach the feared object or event (see Barlow, 1988, for various accounts as to why exposure may work). Exposure may be live (*in vivo*) or imaginal, and with children is generally conducted in a gradual fashion.

The studies reviewed in this section often include an exposure component along with additional cognitive and behavioral strategies. Before discussing this literature, however, several methodological limitations that characterize most of the early studies conducted in this area are worth noting. First, the majority of the treatment outcome studies did not use controled experimental procedures, clinic referred samples, structured diagnostic procedures, multimethod–multisource assessment procedures, or systematic follow-ups (Silverman & Rabian, 1993). In addition, research has insufficiently addressed the relative efficacy of one treatment strategy over another (e.g., cognitive vs. behavioral) or one format over another (e.g., individual vs. group). There has also been very limited research conducted on potential predictors of treatment outcome (e.g., comorbidity, parental anxiety symptoms, treatment duration). Also absent is any type of conceptual framework to help guide clinicians' and researchers' thinking in how to go about developing and implementing intervention approaches for children with SP. With these limitations in mind, a brief overview is presented of the major cognitive and behavioral strategies that have been used in the treatment of childhood SP. A "transfer of control" model is then presented which might serve as a useful framework for developing and implementing psychosocial interventions for children with SP.

The most commonly used cognitive and behavioral procedures that have been used to treat child SP include: systematic desensitization, flooding, modeling, contingency management, relaxation training, and self-control. Descriptions of each of these strategies, along with evidence supporting their effectiveness, have been presented elsewhere (e.g., see King et al., 1988; Silverman & Eisen, 1993), and will not be detailed here.

Among these strategies, contingency management, modeling, and self-control have received the most attention and appear to be the most promising (Morris & Kratochwill, 1983). Briefly, contingency management, based on the principles of operant conditioning, stresses the importance of the causal relation between stimuli and behavior (Morris & Kratochwill, 1983), and relies on the therapist and the parents to rearrange the environment to ensure that positive consequences follow a child's exposure to the fearful stimulus, and to ensure that positive consequences (e.g., attention) do not follow avoidant behavior. Modeling involves the child learning to be less fearful or anxious by observing others handle the fearful object or event. The models observed by the child may be actual, or "live" models, or they may be observed on films or videotapes, or "symbolic" models. Finally, self-control stresses the important contribution of cognitive processes to behavior change and involves the child directly regulating her or his own behavior by applying specific thinking styles when confronted with the fearful stimulus.

All of the above strategies (i.e., contingency management, modeling, self-control), alone or in combination with other strategies, have been found to be effective in treating children who display a wide range of fears including those related to: nighttime (Graziano, Mooney, Huber, & Ignasiak, 1979; Graziano & Mooney, 1980; King, Cranstoun, & Josephs, 1989); darkness (Giebenhain & O'Dell, 1984; Heard, Dadds, & Conrad, 1992; Jackson & King, 1981; Kanfer, Karoly, & Newman, 1975); loud noises (Tasto, 1969; Wish, Hasazi, & Jurgela, 1973; Yule, Sacks, & Hersov, 1974); public speaking (Cradock, Cotler, & Jason, 1978; Fox & Houston, 1981); heights (Croghan & Musante, 1975; Holmes, 1936; Ritter, 1968); animals (Bandura, Blanchard, & Ritter, 1969; Glasscock & MacLean, 1990; Obler & Terwilliger, 1970; Sreenivasan, Manocha, & Jain, 1979); water (Lewis, 1974; Menzies & Clarke, 1993; Ultee, Griffioen, & Schellekens, 1982); menstruation (Shaw, 1990); telephones (Babbitt & Parrish, 1991); newspapers (Goldberg & Weisenberg, 1992); bowel movements (Eisen & Silverman, 1991); needles (Rainwater et al., 1988); medical procedures (Heard et al., 1992; Peterson & Shigetomi, 1981); dental procedures (Krochak, Slovin, Rubin, & Kaplan, 1988; Siegel & Peterson, 1980); traveling in cars (Stedman & Murphy, 1984; Thankachan, Mishra, & Kumaraiah, 1992); and illness/diseases (Hagopian, Weist, & Ollendick, 1990).

In an early controlled group treatment study that focused on treating childhood phobia, Miller et al. (1972) randomly assigned phobic children ($N = 67$; aged 6–15 years) (67% had a primary fear of school) to one of three treatment conditions: reciprocal inhibition ($n = 21$), play therapy ($n = 23$), and a waitlist control ($n = 23$). Treatment was provided three times a week for eight weeks. Outcomes, based on parent and clinician reports, revealed no significant differences between the two treatment conditions, but children in both treatment conditions improved relative to the children in the waitlist control. Moreover, an examination of children in both active treatments revealed that younger children (aged 6–10 years) appeared to evidence significantly greater improvements relative to older children (aged 11–15 years) in both conditions.

Menzies and Clarke (1993) compared three fear-reduction strategies for children ($N = 48$; aged 3–8) with water phobia. Children were assigned randomly to one of four groups: (i) *in vivo* exposure plus vicarious exposure (watching a model), (ii) vicarious exposure only, (iii) *in vivo* exposure only, and (iv) assessed only. All children received three treatment sessions and assessments were based on the following: behavioral tasks in water (children asked to engage in different tasks of varying difficulty level such as stepping into a pool, putting their face under water, etc.); self-ratings of water fears; and a combined observer and clinician rating of the children's overall reactions to the phobic situation while the child was engaged in completing tasks in the pool. On all measures, the results revealed that the children in both exposure groups (groups i and iii) improved relative to the assessed only and vicarious only (groups ii and iv). No differences were found between the exposure groups (group i and iii).

The authors, in collaboration with others at the Child and Family Psychology Social Research Center, completed a controlled clinical trials study for children with phobic disorders. This study compared the relative effectiveness of an exposure-based contingency management (CM) treatment, an exposure-based self-control (SC) treatment, and an education-support (ES) comparison condition in which exposure was discussed but was not directly prescribed (such as through CM or SC procedures). A total of 99 children (aged 6–16 years; mean age = 9.9 years) and their parents participated in the study. Fifty-two were boys and 47 were girls. All children met criteria for a primary *DSM-III-R* diagnosis for phobic disorder, including SP ($n = 82$), SOP ($n = 10$), or AG ($n = 7$), based on a structured interview administered separately to the child and parent.

Each of the 99 children and their parents were assigned randomly to one of the three conditions. There were 37 children in the CM condition, 40 in the SC condition, and 22 in ES. Each condition was a 10-week treatment program in which the children and parents were seen in separate treatment sessions with the therapist, followed by a brief conjoint meeting. Results indicated that all the procedures that were used to facilitate the occurrence of exposure, the CM condition, the SC condition, as well as the ES condition, produced effective therapeutic change on all of the main outcome measures (child, parent, and clinicians), including the indices of clinically significant change (i.e., percentage of children who no longer met diagnostic criteria). More impressively, these gains were maintained at three, six and 12 months follow-up. The findings are discussed within the context of the transfer of control model, described in Section 5.14.7.1.

5.14.7.1 Transfer of Control Model

According to the transfer of control model, the therapist is viewed as an expert consultant who possesses knowledge of the skills and methods necessary to produce long-term child therapeutic change. Effective change involves a gradual transfer of the knowledge, skills, and methods from the therapist to the parent to the child (Silverman & Kurtines, 1996). In treating children with SP, the focus of treatment is on controlling the occurrence and successful implementation of exposure to the feared object or situation. Based on findings from our treatment outcome study, it is believed that there are several strategies that might be used to facilitate an adequate transfer of control. These include a more parent-focused treatment, such as CM; a more child-focused treatment, such as SC; a combination (CM followed by SC); a less prescribed strategy, such as ES; a group treatment strategy (Ginsburg, Silverman, & Kurtines, 1995a), and even, perhaps, a format that involves a more thorough and systematic intervention on the child and parent relationship or to what is referred to as "dyadic treatment" (Ginsburg, Silverman, & Kurtines, 1995b). The task ahead for clinicians and researchers is to delineate the particular pathway (and thus, treatment strategy or format) that might be most useful for a child with SP and their family.

5.14.8 CASE STUDY

5.14.8.1 Presenting Problem

Jody, a 12-year-old Caucasian boy, was presented by his mother because of his extreme reactions to thunderstorms. She described that on cloudy or rainy days her son would repeatedly ask questions about the weather, watch only the weather channel on TV or listen to the weather radio, report somatic complaints, and generally appear tense and nervous. During thunderstorms, (a common occurrence in South Florida), Jody would scream, cry, and run and hide in his closet. In addition, Jody would refuse to go outside (e.g., to the mailbox, car, mall, etc.) and refused to sleep alone in his room. Although Jody's mother reported that he was always a worrier, his reactions to thunderstorms (and apprehensions about other natural disasters such as tornadoes) had increased dramatically within the past year and were significantly interfering with his and the family's functioning.

5.14.8.2 Assessment and Diagnosis

Jody and his mother were administered respective child and parent versions of the ADIS-C and ADIS-P. Jody also completed several self-rating scales, and he was administered an *in vivo* behavioral task during which time his heart rate was monitored. As noted above, Jody's mother reported that his fearful and avoidant behavior was interfering with various aspects of his and the family's life. For instance, his school performance had begun to decline because he was having difficulty concentrating in school when storms were approaching. Socially, Jody's fears prevented him from going on outings (e.g., fishing, camping) and he had begun to run off the playing field during his little league games if he saw lightning or heard thunder. At home, Jody's fear often prevented the family from completing errands or attending activities if a storm was approaching.

Based on Jody and his mother's responses to the interviews, Jody was assigned a diagnosis of SP, natural environment subtype. On the ADIS-C/P, both Jody and his mother reported that his fear of thunderstorms was a "7" on the 8-point fear thermometer. His scores on the questionnaires were also elevated. Jody's *in vivo* behavioral exposure test, which required him to walk outside with the therapist during an afternoon thunderstorm for five minutes, was terminated because he became too upset.

5.14.8.3 Treatment

Jody was enrolled in a 10-week exposure-based treatment program in which parent and child were seen individually and then briefly together. The program, based on the transfer of control model, involved first teaching Jody's mother the principles of contingency management and then teaching both Jody and his mother child self-control strategies. These strategies were then applied in gradual exposure tasks that involved Jody gradually approaching going outside during storms.

Exposure tasks were both imaginal and *in vivo* and were based on a hierarchy that varied how close to being outside Jody would get during thunderstorms. Initial *in vivo* steps on the hierarchy, during which Jody remained outside of the closet but inside the house during a storm, were successful, but as the exposures became more difficult, requiring him to go outside, Jody was unable to complete the exposures and explained to the therapist that storms were just too unpredictable. In discussing these difficulties with Jody's mother, she indicated that she felt Jody's fears were not totally irrational. Many Florida residents had lost their homes during Hurricane Andrew in 1992 and there had been recent incidents of tornadoes in the news.

To deal with these concerns, subsequent treatment sessions addressed some of the common obstacles encountered with treating SP. For instance, emphasis was placed on reviewing with Jody's mother the importance of parental modeling of courageous behavior. In part, this was accomplished by discussing common parental "protective behaviors" and her own fears related to hurricanes. In addition, Jody and his mother were helped to think of alternative ways of handling their fears, including specific steps they could take so that they could be maximally prepared for hurricanes. This included obtaining accurate information about hurricane preparedness and warnings (e.g., that although hurricanes are uncontrollable, there is usually plenty of advance warning and time to prepare). This approach helped to empower the family and enabled them to have an "action plan" if Jody's worst fears were to materialize (e.g., that a hurricane was forecast). All of these methods were helpful and subsequent contracts were successfully carried out, including the one that required him to go fishing with his grandfather on a rainy day.

In the final phase of the transfer of control, wherein self-control strategies were used (including self-reward to replace parental rewards), Jody practiced examining the specific cognitions which played a role in maintaining his fear (e.g., "the hurricane will blow my house away"). Jody learned to recognize when he was afraid or worried, to employ more adaptive coping thoughts and behaviors, and to praise himself for doing so.

5.14.8.4 Post-treatment and Follow-up

At post-treatment assessment, readministration of the relevant sections of the ADIS-C and ADIS-P revealed that Jody no longer met criteria for SP and there was no longer any interference in his daily functioning. In addition, his scores on the questionnaires decreased markedly and Jody was able to do the behavioral exposure test. These gains were maintained at three and 12-month follow-up assessments.

5.14.9 SUMMARY

This chapter presented an overview of what is known about specific phobias in children, beginning with a discussion about phenomenology, including variations which may be associated with age, gender, and race/ethnicity. Information about the onset and stability, diagnostic criteria, and issues related to differential diagnosis was presented. Thinking about etiology, both biological and psychosocial perspectives, was presented next. This was followed by a summary of the epidemiological data which indicate an average prevalence rate of about 2–9% (based primarily on Caucasian community samples). The chapter discussed assessment and treatment procedures that have been found useful for working with children with specific phobias, including the evolving transfer of control model as a possible framework to help guide clinicians' and researchers' thinking in how to develop and implement interventions. A case study was presented to illustrate the issues discussed.

5.15.1 INTRODUCTION

The development of the current conception and classification of what we know as "obsessive-compulsive disorder" (OCD) has been full of controversy. While this fact in itself is not extraordinary in the area of psychopathology, it is remarkable that many of the historical controversies are still alive and some are even kicking. The disorder has proved particularly difficult to define and classify. This has to do with the fact that it involves, or is associated with, various functions and dysfunctions of mind and behavior. It evidently involves the intellect, with thoughts or doubts at or beyond the border of sanity; it frequently involves the emotions, particularly fear and melancholia; it typically involves an apparent impairment of the power of the will, with distressing thoughts and actions persisting against the person's wishes; the behavioral aspects of the disorder are in some cases akin to complex tics, or even to motor movements induced by brain seizure. The development of the current concept of OCD reflects all the various possibilities which this complex phenomenology opens up. Many early psychopathologists tackled the problem, including, for example, Esquirol, Morel, Dagonet, du Saulle, and Ball, in France, Krafft-Ebbing, Westphal, and Wille, in Germany, and Mickle, Tuke, and Jackson, in Britain (Berrios, 1995). During the nineteenth century particularly, what we now know as OCD was alternatively conceived as a disorder of intellect, volition, or emotions, and classified variously along with psychoses, neurologically based motor disorders, and anxiety disorders. The conception of OCD as primarily a disorder of the emotions, and its classification along with typical anxiety disorders, were consolidated during the early twentieth century and were embraced by the major nosological systems, where they remain today enshrined in the most recent editions, *DSM-IV* (American Psychiatric Association, 1994) and *ICD-10* (World Health Organization, 1988). The conception of OCD as an anxiety disorder was consistent with and reinforced by psychoanalytic theory, and it is equally well-suited to behavioral and cognitive behavioral theorizing.

However, major controversies have appeared, or more accurately reappeared, concerning the nature and appropriate classification of OCD. There has been a resurgence of interest in the notion of a spectrum of OCDs within which typical OCD is one kind of case, but which includes conditions other than anxiety disorders. Further, there is a view which has assumed something of the status of an orthodoxy, particularly in the United States, to the effect that the primary dysfunction in OCD is more to do with motor control than with emotional conflict, and that both motor and psychological aspects of the disorder probably cannot be understood in terms of psychological principles, whether psychoanalytic or cognitive-behavioral, since they are due to an hypothesized structural or biochemical neural lesion.

Notwithstanding theoretical uncertainty, progress on the treatment front has been substantial. OCD had been found to be refractory to psychiatric treatments, though some cases showed reasonably good response to psychosurgery, and also resistant to psychoanalysis (Rachman & Hodgson, 1980). The first studies of the course of the disorder showed reasonably good recovery in as little as a third of cases. The position was transformed, however, in the late 1970s and early 1980s, with the development of two new forms of treatment: behavior therapy—specifically exposure with response–prevention—and pharmacotherapy using agents which specifically inhibited uptake of the neurotransmitter serotonin. Trials of these two new forms of treatment, separately or in combination, found good outcome in up to two-thirds of cases. There is thus reason now to be fairly optimistic about prognosis. There is, on the other hand, ample scope for more improvement in a number of areas: in cases where the person has insufficient motivation for behavioral treatment, where there is poor response to treatment, and where there is subsequent serious relapse. In other words the current forms of treatment constantly come up against their limitations, and this requires not only continuing attention to therapeutic details and refinements, but also continuing work on the complex and controversial models of the etiology of the disorder.

5.15.2 OBSESSIVE-COMPULSIVE DISORDER

5.15.2.1 Phenomenology

As a young child, Christine used to worry occasionally about germs, afraid that she would infect other people or vice versa. At age 12 following the death of a family friend Christine was very upset and began washing her hands excessively. A few months later she became preoccupied with thoughts about lines which had to be unwoven by retracing her steps, and this inhibited her from going out. Age 13, Christine's paternal grandmother died of cancer, and she began menstruation during the same year. Over this time Christine became increasingly preoccupied with intrusive, distressing thoughts which usually had violent or sexual content. If a sexual or violent thought occurred in her mind, she would feel compelled to return to the place she had just been, or stage in a behavior sequence, and then move forward again without having the thought, which procedure she felt neutralized having the thought in the first place. In practice, this meant that she would take up to several hours to walk a short distance or get dressed. Christine would spend much time telling her mother of her thoughts, or being helped by her mother to restart activity when she got stuck.

John was referred at two and a half years to a child guidance clinic because of parental concern over his failure to socialize with other children, speech delay, and concern about possible mental retardation. He was clingy with his mother and was never able to dress himself fully. Later at school John was reported to be polite, cooperative, and of slightly above average intelligence. However, he was said to be "painfully slow" and a backward reader with barely legible writing. John was socially isolated, teased, and harassed by his peers. Following entry into secondary school John's difficulties worsened, and at age 11 he was admitted for several weeks to an inpatient psychiatric unit. He presented as a prepubertal boy with faint and hesitant speech. He was severely slow in all his personal functions, requiring the nurses to dress, wash, bathe, and help him eat. If left on his own, he took six to eight hours to dress and often stood motionless for long periods of time being distracted by something irrelevant to the task. He was frequently incontinent due to his slowness. He walked with a skipping gait, and had multiple tics and mannerisms such as squinting his eyes, tapping his hands, touching his right cheek with his left hand, licking his lips, and producing repetitive writhing neck movements, and jerking action of his upper limbs. When leaving a room John would repeatedly tap the door to ensure it was closed, he checked his knife and fork for dirt, and turned his head before starting to walk. John was often preoccupied with the correct manner of performing a task, being fearful he would make a mistake and thus feel compelled to return to the beginning of the sequence. He said he did not resist his habits and felt more anxious when prevented from performing them. He used "magical numbers," often having to tap his hands and feet in sixes and sevens.

These two short descriptions of actual cases illustrate some of the variety of phenomenology in children and adolescents suffering from OCD. There are common features, captured in general terms by the standard diagnostic systems, to be discussed below, but within these broad guidelines there are quite wide variations. With children and adolescents, as for adults with OCD, cleaning compulsions, linked to obsessions about contamination, and checking compulsions, linked to fear of more or less well-specified disasters, are most common. Other common compulsive activities include putting things in a set order, pattern or sequence, either physical or mental, touching, and hoarding (Foa & Kozak, 1995; Riddle et al., 1992; Swedo, Rapoport, Leonard, Lenane, & Cheslow, 1989; Thomsen & Mikkelsen, 1991).

Broadly speaking the phenomenology of OCD is fairly constant through the age range from childhood to adulthood, and this is reflected in the fact that the diagnostic criteria apply across the age range. While the form of the disorder remains essentially the same, some variations in content can be seen. These are generally understandable in biological or psychosocial terms. For example, children and adolescents commonly present with compulsive checking of homework, or with persistent, distressing requests for parents to reassure them that they are safe, and while sexual obsessions are common in adults (Foa & Kozak, 1995; Stern & Cobb, 1978), they are uncommon in children.

As to cultural factors, there is a reasonable amount of data on cultural factors affecting normal childhood fears, but there is little in relation to pathological fear, including obsessional anxiety (Fonseca, Yule, & Erol, 1994). Research on cultural factors affecting OCD has been on adults, and generally the findings are that the disorder presents in similar ways in various cultures, though it remains possible that the content of obsessions and the nature of compulsions may be sensitive in some degree to cultural norms and preoccupations. Most attention has focused on the sometimes very striking apparent similarities between OCD and religious beliefs and rituals, but this alongside the fact that within religions it is explicitly acknowledged that observance to the law can go, as it were, over the top, being no longer piety, but eccentricity or sickness, and in any case usually something to be avoided. This kind of picture has been noted in many countries and religions including Judaism (Greenberg, 1984; Suess & Halpern, 1989), Islam (Mahgoub & Abdel-Hafeiz, 1991; Pfeiffer, 1981), Catholicism (Suess & Halpern; 1989), and Hinduism (Chakraborty & Banerji, 1975; Sharma, 1968). There is, on the other hand, so far no evidence that the extent of religious belief or ritual in a culture affects the risk for developing OCD, at least in the sense that studies in a fairly wide variety of cultures converge on similar figures for prevalence of the disorder (see Section 5.15.2.4).

5.15.2.2 Diagnostic Features

The diagnostic criteria for OCD as specified by *DSM-IV* (American Psychiatric Association, 1994) may be summarized as follows. The person must have either or both of *obsessions* or *compulsions*. "Obsessions" are defined as recurrent, intrusive, distressing mental events, which are not just excessive real-life worries, which the person tries to ignore or suppress or neutralize, and which the person regards as the product of their own mind. "Compulsions" are defined as repetitive behaviors or mental acts carried out in response to obsessions, or according to rigid rules, aimed at reducing distress or averting some dreaded event in the absence of a realistic connection between the activities and the intended consequences. *DSM-IV* specifies that at some point these must have been recognized as excessive or unreasonable, but adds that this criterion need not apply in the case of children. As usual in *DSM-IV*, there is an additional criterion that the symptomatology causes marked distress, is time-consuming, or causes impaired functioning. There is a standard rule specifying that the diagnosis should be made only if the disturbance is not due to the direct physiological effects of a substance or a general medical condition. There is also a further rule excluding the diagnosis of OCD if there is another Axis I disorder present and if the content of obsessions or compulsions is restricted to it, for example, preoccupation with food in the presence of an eating disorder; hair-pulling in the presence of trichotillomania;

concern with appearance in the presence of body dysmorphic disorder; preoccupation with having a serious illness in the presence of hypochondriasis; preoccupation with sexual urges in the presence of paraphilia; or guilty ruminations in the presence of major depressive disorder.

This type of exclusion rule is legitimate, and indeed inevitable, as a means of defining precisely the boundaries of a particular diagnostic category, but of course they might be artificial. Such rules cannot preempt the question whether OCD as so defined is a distinct biopsychological entity compared with the other disorders to which it is apparently related. This bears on the question of "obsessive-compulsive spectrum disorders" to be discussed in Section 5.15.2.5.

ICD-10 uses similar diagnostic criteria (World Health Organiztion, 1988, p. 143). It specifies minimum duration of two weeks, and it defines subtypes of predominantly obsessions, predominantly compulsions, mixed obsessions and compulsive acts, other OCDs, and unspecified.

Foa and her colleagues conducted a field trial involving 431 patients diagnosed as having OCD in seven sites with the aim of examining some empirical and conceptual assumptions of the *DSM-III-R* criteria for OCD and making recommendations for *DSM-IV* and comparisons with *ICD-10* (Foa & Kozak, 1995; with author list correction in Foa et al., 1995). Three issues were examined: (i) the requirement that symptoms of OCD be viewed by the patient as excessive or unreasonable, (ii) the presence of mental compulsions in addition to behavioral compulsions, and (iii) validity of *ICD-10* subcategories. Primary measures were the Yale–Brown Obsessive-Compulsive Scale and face-valid questions about fixity of obsessive-compulsive beliefs. A wide range of views about the unreasonableness of obsessional fears was found among 250 participants: 13% were certain that feared consequences of not performing their compulsions would not occur; 27% were mostly certain; 30% were uncertain; 26% were mostly certain that the feared consequence would occur, and 4% were completely certain that it would occur. Eight percent were classified as currently lacking in insight, and 5% had never recognized the senselessness of their symptoms. The investigators noted that the 5% of patients who reported never having had insight, and perhaps also the 25% who were mostly certain that their symptoms were reasonable, would not formally meet *DSM-III-R* criteria for OCD, and inferred that the participating clinicians with extensive experience with OCD were compensating for imperfections in those criteria. It was subsequently proposed that the requirement for insight should be de-emphasized in *DSM-IV*, and a specifier "with poor insight" has been included. It was found that almost 80% of the patients reported having both mental and behavioral compulsions, and the *DSM-III-R* wording has been clarified in *DSM-IV* to make it clearer that compulsions can be mental and not just behavioral. The authors note that the identification of mental compulsive rituals is important for at least two reasons. First, it can eliminate confusion between OCD and other disorders involving ruminations, such as generalized anxiety disorder or depression; only individuals with OCD perform mental rituals. Second, behavior therapy uses very different techniques for obsessions on the one hand and mental rituals on the other; prolonged exposure is used for the former, and blocking techniques for the latter. Findings on the validity of the *ICD-10* subcategories of OCD were equivocal.

5.15.2.3 Differential Diagnoses

It would be fair to say that most of the time diagnosis of OCD is relatively straightforward, but there are some crucial and interesting kinds of cases in which differential diagnoses have to be considered, and the following are the most common and important.

(i) Ruminative brooding with depressed content may be part of a depressive syndrome rather than obsessions in the sense of OCD. Mood congruence so far suggests depressive disorder.

(ii) Anxious mental preoccupation may indicate generalized anxiety disorder (GAD) rather than OCD. Here a critical feature is that in GAD, worrying is seen as excessive but realistic, while in OCD mental preoccupation is unrealistic. However, the line may be difficult to draw, for example, over worry about parental health.

(iii) There is a fine line, at least in theory, between obsessions and delusions. Both are unreasonable, and may be bizarre, with the critical difference traditionally being that obsessions as opposed to delusions are recognized as such (Berrios, 1995). However, this condition is absent in many adult patients with OCD (Foa & Kozak, 1995; Stern & Cobb, 1978), and as already indicated *DSM-IV* has dropped it altogether for children. Differential diagnoses of OCD and psychoses specifically in adolescents is discussed by Thomsen (1992).

(iv) Stereotyped, repetitive behaviors of individuals with very low intelligence, tic disorders, or pervasive developmental disorders may resemble the compulsive behaviors characteristic of OCD. Some typical differences in the content of repetitive thoughts in autism and OCD have been reported in adults (McDougle et al., 1995), although content is not relevant to diagnosis. So far as concerns repetitive behaviors, the differences critical to diagnosis are that obsessive-compulsions are carried out in response to obsessions or according to strict rules, they relieve anxiety, and they generate distress.

One or more of these features is absent in nonobsessional, stereotyped, repetitive behaviors associated with autism (Baron-Cohen, 1989), mental retardation (Bodfish et al., 1995; Vitiello, Spreat, & Behar, 1989), and tics (Cath et al., 1992; Miguel et al., 1995a).

Decision as to appropriate diagnosis in these various kinds of cases requires careful investigation of phenomenology and the pattern of symptomatology as a whole. If two sets of diagnostic criteria are satisfied, then both diagnoses can be appropriately given, though this is subject to priority and exclusion rules in particular (versions of) diagnostic systems. Comorbidity is common in OCD, in children and adolescents as in adults. Other psychopathology has been reported in up to three-quarters of child and adolescent cases, with other anxiety disorders and affective disorders being the most common (Flament et al., 1988; Riddle et al., 1990; Swedo, Rapoport, Leonard, Lenane, & Cheslow 1989; Valleni-Basile et al., 1994).

5.15.2.4 Prevalence

Early estimates of the prevalence of childhood and adolescent OCD ranged between 0.2% and 1.2% of hospital clinic populations (Berman, 1942; Hollingsworth, Tanguay, Grossman, & Pabst, 1980; Judd, 1965) while the first community study found a 0.3% prevalence of "mixed obsessional/anxiety disorders" in 10 and 11 year-olds (Rutter, Tizard, & Whitmore, 1970). Community studies in the late 1980s and early 1990s estimated life-time prevalence of the disorder by adolescence at 1.9% (Flament et al., 1988) and 3% (Valleni-Basile et al., 1994; with correction in Garrison et al., 1995). Adult community studies have estimated 2–3% for life-time prevalence of the disorder in the United States (Karno, Golding, Sorenson, & Burnam, 1988; Robins et al., 1984), with comparable estimates in some other countries and cultures including Uganda (Orley & Wing, 1979) and Canada (Bland, Newman, & Orn, 1988), though with a lower estimate (approximately 1%) in Taiwan (Hwu, Yeh, & Chang, 1989).

As to age of onset, OCD can start very early in childhood, with cases of children below six and as young as three years described in the literature (Adams, 1973; Janet, 1903; Rettew, Swedo, Leonard, Lenane, & Rapoport, 1992). Childhood OCD typically onsets between five and eight years of age or during adolescence (Swedo, Leonard, & Rapoport, 1990), and the age of onset is below 25 years and mostly during adolescence in approximately two-thirds of adult cases (Kringlen, 1965; Pollitt, 1957; Rasmussen & Eisen, 1990). Rasmussen and Tsuang (1986) found two peaks of maximal incidence of the disorder, one at 12–14 years and the other at 20–22 years.

The fact that OCD can often have onset in young children is relevant in several ways to a developmental perspective on etiology. The apparent implication is that whatever maturation has to be reached for the disorder to appear, biological or psychological or both, has already been reached relatively early in childhood. At the same time OCD is apparently not a "developmental disorder": it does not obviously involve any specific developmental delay, and moreover, it can have late onset, in teenage or early adulthood, or beyond. It is also noteworthy that childhood obsessive-compulsive symptomatology appears at around the same time as normal childhood magical thinking and behavior (Gesell, Ames, & Ilg, 1974; Harris, 1994), and the two sets of phenomena—the one psychopathological and the other belonging to normal psychological development—have at least some superficial resemblances; both involve irrational beliefs and the carrying out of rituals aimed, for example, at averting feared outcomes. The exact relevance of these superficial resemblances to the nature of OCD remains controversial, however, and it is discussed further along with other developmental issues in Section 5.15.2.5.

5.15.2.5 Etiology

Accompanying the vigorous interest in OCD there has been much research and theorizing about etiology. The research programmes are of various types, described as psychological, neurological, biological, ethological, or as various compounds of these.

"Psychological" models are characterized by appeal to learning processes involving conditioning or the more complicated information-processing envisaged in the newer cognitive psychological paradigm. There have been many psychological models of OCD, critically reviewed by Jakes (1996), and what follows is a partial review of some main points. For the most part the psychological theories involve variations and elaborations on the themes of neurotic anxiety in combination with active but maladaptive anxiety reduction. This approach to the disorder is obviously linked closely to its typical phenomenology and its classification among the anxiety disorders. A significant exception to this approach is the hypothesis that the core psychological process in OCD is a memory dysfunction leading specifically to chronic doubting and checking (Boone, Ananth, Philpott, Kaur, & Djenderedjian, 1991; Reed, 1977; Sher, Frost, & Otto, 1983). Evidence relating to this hypothesis is conflicting (Martin, Wiggs, Altemus, Rubenstein, & Murphy, 1995; Tallis, 1995), but it plays a role in neuropsychological theorizing which is discussed later in this section.

Otherwise most psychological theories of OCD have emphasized anxiety and anxiety reduction. Obsessions are regarded as expressions of extreme and inappropriate anxiety, and compulsions as strategies for reducing it. Questions then immediately arise as to (i) why the person has such excessive anxiety, and (ii) why an apparently nonsensical, repetitive procedure should reduce it. These are the etiological questions formulated from within this conception of OCD. From the beginning of psychological theorizing about anxiety disorder, there was a clear assumption in both the psychoanalytic and conditioning paradigms that excessive anxiety is generated by trauma and resulting conflict among cognitive-affective states. Applied to obsessional neurosis, the implication is that the patient has experienced or is experiencing some form of trauma, the likely candidate being experience of being out of control over highly salient events (Freud, 1913; Rachman & Hodgson, 1980). As to ritualizing, Freud went on to observe that compulsive anxiety-reducing strategies apparently draw on prerational, magical styles of thinking (Freud, 1913). The basic idea is that, in the absence of real control over salient matters (such as illness and death), helplessness and anxiety can be avoided by taking control over something more within one's power, such as the way food is prepared, or counting in a set pattern. Symbolic power to reduce anxiety would be reinforced by real power according to simple principles of operant conditioning. Cognitive-behavioral theorists have envisaged these kinds of mechanisms as being also involved in the generation and maintenance of OCD (Franzblau, Kanadanian, & Rettig, 1995; Pitman, 1987; Rachman & Hodgson, 1980).

It is a relatively weak claim, though one which can be challenged, as will be considered below, that compulsions reduce the anxiety associated with obsessions and are thereby maintained. It is a much stronger and more controversial hypothesis to suppose that, notwithstanding appearances, obsessions signify anxiety which is in some sense realistic, specifically fear of being unable to control biopsychologically salient events. For what are these hypothesized events? Pitman (1993) notes evidence of raised rates of OCD among high-combat-exposed Vietnam veterans and discusses the case of a man without previous psychopathology who under combat stress developed persistent OCD as well as post-traumatic stress disorder. He observes that if one focuses on counting the feet of the war dead—one of the patient's counting compulsions—at least one avoids looking at their faces (Pitman, 1993, p. 106). However, it is plain that such cases are not the rule, that in most cases of OCD there is no obvious trauma which might help explain onset in this kind of way. Often no precipitating event is reported by the person or family, or reported precipitants are common life events (Rettew et al, 1992; Valleni-Basile et al., 1995), although common stressful events typically exacerbate symptoms in children and adolescents (Swedo, Rapoport, Leonard et al., 1989), and in adults (Rasmussen & Tsuang, 1986). Nor is it clear that adverse parenting experiences are implicated in the development of OCD. Speculation that parents of children who develop OCD are overstrict has not been borne out in any clear way (Judd, 1965; Merkel, Pollard, Wiener, & Staebler, 1993; Valleni-Basile et al., 1995). Hibbs et al. (1991) found raised levels of "expressed emotion" in families of children with OCD, but this phenomenon is known to be associated with a variety of disorders.

The upshot of all this is that the best candidates for highly anxiogenic experiences associated with OCD are likely to be in large part intrapsychic, to do with the individual's interpretation of otherwise ordinary events. One possibility which remains popular since Freud is that the person who develops OCD has particular difficulty managing high levels of negative emotion, such as is linked to loss or aggression, and hence feels out of control when faced with these emotions, and distracts from and temporarily remedies this threatening helplessness by obsessions and compulsions. The findings most relevant here have been on the excessive worrying characteristic of generalized anxiety, with indications that worrying can function as a mechanism for avoiding accessing and processing emotionally relevant information, in adults (Borkovec & Inz, 1990) and in children (Keppel-Benson & Ollendick, 1993; Vasey, 1993). It is likely that intrapsychic avoidance in the child would reflect avoidance of similar emotionally relevant material in the family (Bolton, 1995). Insofar as excessive worrying is systematically associated with obsessional symptomatology (Tallis & de Silva, 1992), it is possible that obsessional thinking and behavior may serve a similar function as worrying, serving to avoid negative emotional states (Schut & Castonguay, 1996).

The view of OCD as fundamentally involving anxiety and anxiety reduction, particularly insofar as the anxiety has predominantly intrapsychic origins, can be elaborated in various ways in the cognitive paradigm. Carr (1974) emphasized the unrealistic threat appraisals in the disorder. McFall and Wollersheim (1979) highlighted various kinds of dysfunctional assumptions such as that one should be perfect, that mistakes should result in condemnation, that the self is powerful enough to prevent disasters. This approach explores the important possibility that what is abnormal in OCD is not the manifest symptomatic thoughts, but is rather the sometimes less apparent assumptions behind, or appraisals of, these thoughts. Another approach along these lines proposes that an inflated sense of responsibility plays a critical role in the generation of OCD (Salkovskis, 1985). This model begins with the fact that everyone has normal, unwanted, intrusive thoughts, and supposes that people with OCD place special significance on these thoughts, perhaps because OCD sufferers have an exaggerated sense of responsibility. This leads to feeling responsible for producing the thought, to feeling oneself to be a bad person, and to excessive guilt. It may also prompt the feeling that they must act to prevent a feared disaster. The "neutralizing" action results in recurrence of the thought. Thus, there arises a vicious circle involving unwanted, intrusive thoughts, feelings of responsibility and guilt, attempts to neutralize the thoughts, and hence, inadvertently, their recurrence (Salkovskis, 1985). Feelings of responsibility and guilt might be exacerbated particularly in the absence of a clear distinction between having a negative thought, and carrying out the negative action itself, a blurring which has been called "thought–action fusion" (Rachman, 1993). Because these cognitive approaches implicate self-worth, guilt, and failure, they can account for the high association between OCD and depression (Van Oppen & Arntz, 1994).

The earlier psychological models of OCD were developmental in various ways. Insofar as conditioning theory implied early traumatic experience, it was in a primitive sense developmental. In Freud's developmental stage theory, obsessionality was linked particularly to the so-called anal stage, in which anxiety about a particular kind of aggression was prominent, namely, aggressive being out of control of one's own action and thereby making a mess (Freud, 1908). Freud (1913) also construed the irrationality of OCD as a pathological expression of normal childhood magical thinking, as belonging to a prerational stage of thought which is normally later replaced by rational thought. Research has shown that rational grasp of everyday causal principles is evident from very early on, from infancy, while appeal to magic can play a role in the young child's explanations of apparent violations of these principles (e.g., Harris, 1994). Freud's developmental approach to the irrationality in OCD can, however, survive this shift in emphasis away from "stage theories" of cognitive development. Indeed, the developmental approach might if anything be strengthened by it; the fact that in children (as also in so-called "magical cultures") magical thinking can coexist with and to some extent interact with rational thinking is so far compatible with this same pattern in OCD.

The possible link between OCD and childhood magical thinking is also relevant to the cognitive formulations of OCD discussed above. Cognitive styles involving, for example, exaggerated responsibility and thought–action fusion may have their origins in apparently related ways of thinking and states of mind typical of childhood, specifically in the tendency to overestimate the self's power, alongside a not yet firmed-up distinction between thought and action (Piaget, 1937, 1960; Vygotsky 1934).

It is also possible to link a psychological developmental model of OCD with an ethological model. The possibility of viewing at least some obsessive-compulsive behaviors as displacement behaviors in the sense of ethological theory was proposed some time ago by Holland (1974). Displacement behaviors are fixed action patterns carried out in the absence of a normal releasing stimulus, typically in situations of drive conflict or frustration, while fixed action patterns are innate and adaptive motor acts or sequences normally triggered by a so-called releasing stimulus, and include behavioral routines such as pecking, grooming, hoarding, and digging (Lorenz, 1966, 1981; Tinbergen, 1953). An explanation of why fixed action patterns occur in the absence of a normal releasing stimulus, typically in situations of drive conflict or frustration, may be that they have a physiologically low initiation threshold, but it is likely that they then acquire tension reducing, reinforcing functions (Eibl-Eibesfeld, 1970; Lorenz, 1966). Such a process is of course fundamental in evolution and learning; what starts as random, meaningless (nonfunctional) behavior turns out to produce benefits for the organism, typically drive-reduction, and is maintained, intensified, and shaped because of those properties. It seems plausible to suggest that the performance of displacement behaviors when faced with being unable to do anything else functions as an "illusion of control" for the animal. This points towards the area of the developmental cognitive account, and specifically towards the functional benefits of ritualized thinking and behavior already discussed.

It is possible in this way to piece together a psychological model of OCD which integrates a reasonable amount of both early and contemporary theorizing, and which provides that strong kind of biopsychological developmental model which runs seamlessly through phylogenesis and ontogenesis. This kind of model of OCD—sketched in some more detail in Bolton (1996)—is a reasonably good fit with some of the data but not with others. As already remarked, the basic view of obsessions and compulsions fits well because it is based on typical phenomemology. As is also well known, the core of this kind of psychological formulation of OCD—which emphasizes anxiety and its reduction—can provide a reasonable model for the effectiveness of behavior therapy methods, to be discussed later, which consist of methods of anxiety-reduction and the acquisition of more adaptive coping. None of these superficial good fits with the data are at all conclusive support, however. Other aspects of the psychological model as sketched above are doubtful and at best unproven, including, as discussed above, the hypothesized experience of being out of control over negative salient events, the link between OCD and normal developmental childhood magical thinking (Leonard 1989; Leonard, Goldberger, Rapoport, Cheslow, & Swedo, 1990), and the role of exaggerated sense of responsibility (Bogert, Katz, Amir, & Foa, 1996; Ladouceur et al., 1995; Van Oppen & Arntz, 1994). A further general problem for developmental accounts of any disorder is how to handle late onset, which in the case of OCD can be well into adulthood.

Relatively good or poor fits with the data are common enough in models of psychopathology, but what is particularly interesting in the case of OCD is the appearance of radical questioning about the orthodox way of looking at things. In its sharpest distinction, the alternative view stands on its head the conventional interpretation of the relation between obsessions and compulsions. It regards compulsive behaviors as primary, as triggered by some kind of neurological deficit, either structural or functional (biochemical) or both, and obsessions as being either mental versions of compulsive behaviors, or as *post hoc* rationalizations of—confabulations about—compulsive behaviors. Versions of this kind of model of OCD have been proposed by Rapoport and her colleagues (Rapoport, 1990; Rapoport, Swedo & Leonard, 1992; Rapoport & Wise 1988), and have been discussed, for example, by Insel and Winslow (Insel, 1988, 1992; Winslow & Insel, 1991). These models propose that the neurological basis of OCD involves cortico-striatal-thalamocortical circuitry, consistent with various lines of evidence including functional brain imaging (Baxter et al., 1988; Lucey et al., 1995; Luxenberg et al. 1988; Swedo et al., 1992; McGuire et al., 1994; Rubin, Villanueva-Meyer, Ananth, Trajmar, & Mena, 1992). The models postulate that structural and/or biochemical lesions in these systems may underlie OCD, and they combine the postulate of neural deficit with the ethological approach to compulsive behaviors, regarding them as akin to displacement activities. However, in the context of neurological deficit models the hypothesis is that these behaviors are triggered meaninglessly, in contrast to the suggestion within psychological models that they are regulated by information, and specifically that they function in the reduction of helplessness and anxiety.

Both Insel and Rapoport also refer to the apparently distinct psychological approach to OCD mentioned earlier, which focuses not so much on the ritualistic resolution of anxiety but more on the chronic doubting which characterizes the disorder. They propose that the basal ganglia, as well as regulating displacement/compulsive behaviors, may also be implicated in the resolution of doubt, and hence that lesions in these same structures may lead to the chronic and extreme skepticism characteristic of OCD (Insel, 1988; Rapoport, 1990).

Various kinds of evidence have been cited in support of the view that a neurological deficit underlies OCD. Association between obsessive-compulsive symptomatology and known as cerebral disease has long been known, particularly the case of encephalitis lethargica (von Economo, 1931), though also Sydenham's chorea (Grimshaw, 1964; Swedo, Rapoport, Cheslow et al., 1989), and multiple sclerosis (Miguel et al., 1995b). There is also association between obsessive-compulsive symptomatology and suspected signs of cerebral disorder, specifically tics (Como, 1995; Pauls, Alsobrook, Goodman, Rasmussen, & Leckman, 1995; Santangelo et al., 1994), and it occasionally appears following head injury (Jenike & Brandon, 1988; Max et al., 1995; McKeon, McGuffin, & Robinson, 1984). OCD sometimes responds to psychosurgery (Chiocca & Martuza, 1990; Hay et al., 1993). Further evidence of abnormal neurological involvement in OCD is well-replicated above normal frequency of neurological soft signs, and not so well replicated below normal performance on neuropsychological tasks such as tests of complex spatial and switching ability (Abbruzzese, Ferri, & Scarone, 1995; Alarcon, Libb, & Boll, 1994; Christensen, Kim, Dysken, & Hoover, 1992; Cox, Fedio, & Rapoport, 1989; Denckla 1989; Head, Bolton, & Hymas, 1989; Hollander et al., 1990; Hymas, Lees, Bolton, Epps & Head, 1991; Max et al., 1993). The most direct evidence of abnormal structural neurological involvement OCD is structural abnormalities detected by computed tomography (CT) or magnetic resonance imaging (MRI), though the findings here are conflicting (Hoehn-Saric & Benkelfat, 1994; Peterson, 1995; Robinson et al., 1995).

Apart from the equivocal structural scan results, the evidence for neurological deficit in OCD can be seen to be circumstantial and something of a mixture. Nor is it the case that the various signs of neurological disorder hang together. For example, in the above cited studies, the extent of neurological soft signs typically do not correlate with the extent of impairments on neuropsychological tests. In an interesting study of various commonly accepted signs of organic dysfunction, such as birth complications and neurological signs, in 61 children and adolescents with OCD and a psychiatric control group, Thomsen and Jensen (1991) found that a latent class analysis assigned fewer OCD children than control patients to the "organic" class, and concluded that the disorder did not depend on cerebral disturbance as detected by conventional neuropediatric methods.

As already indicated, there is the possibility of a specific biochemical abnormality in OCD. The disorder is highly selective in its response to psychotropic medication, suggesting a relatively circumscribed underlying neurochemistry. Most medications which are effective in the treatment of anxiety, depression, or psychosis are generally ineffective for OCD. The only drugs shown so far in group studies of various designs to be effective in the treatment of OCD are the potent inhibitors of synaptic uptake of serotonin (SRIs) (Piccinelli, Pini, Bellantuono, & Wilkinson, 1995; Stein, Spadaccini, & Hollander, 1995). The role of serotonergic fibers in mediating specific behavior remains speculative, however, though there is some evidence that serotonin has a prominent role among the brain mechanisms which may modulate aggressive behavior (Insel & Winslow, 1992). It is also notable that SRIs have been shown to be effective in the treatment of anxiety disorders other than OCD, in adults and in children (Birmaher et al., 1994; Schneier, Chin, Hollander, & Liebowitz, 1992) and this is consistent with the possibility that their effect in OCD is mediated by an effect on anxiety.

In this context a general point can be noted about the links between abnormal neurological function associated with a disorder, such as abnormal biochemistry or regional glucose metabolism, and "neurological deficit." The main point is that the former does not entail the latter. In brief, abnormal neurological function (in the sense of difference from that associated with no psychopathology) is so far quite compatible with the hypothesis that the disorder involves and is best explained in terms of psychological processes (intentionality, learning, information-processing, etc.). There is no legitimate inference from neurochemical or functional imaging findings to "neurological deficit," if this is understood as meaning that psychological processes and explanation have come to end (as they have in epilepsy, for example). There are complicated issues here to do with the logic of explanation of mental order and disorder, discussed in detail in Bolton and Hill (1996).

To summarize, research programs have focused on various aspects of OCD, including basic psychological processes involved, precursors in phylogenesis, models of how these map onto and are realized by neural structures and functions, and cutting across those topics there is apparent disagreement as to whether etiology can be understood in terms of biopsychological principles (such as adaptation to perceived loss of control) or whether the disorder is mainly a matter of a neurological lesion causing meaningless compulsions and confabulating obsessions. It would be fair to conclude that the etiology of OCD remains in fundamental ways uncertain. The traditional model of OCD and its various expressions in the broad cognitive psychological paradigm have a great deal of plausibility and evidence on their side. They do not, however, predict the array of findings which seem to implicate a neurological deficit. On the other hand, neurological deficits have not yet been definitely identified, and the possible interactions with psychological processes and symptomatology remain speculative.

In the background is the question whether OCD as a nosological entity will correspond to a "kind" in terms of psychological, biological, or neurological theories. It is possible from any or all those points of view that, on the one hand, subtypes of OCD may be significantly different, and on the other hand, that OCD may not be fundamentally different from some other disorders. Concerning neurobiological aspects of OCD, Insel and Winslow (1992) conclude that subgrouping based on such symptom types, character style, or comorbid diagnoses will be increasingly important for understanding the results of neuropharmacological and functional imaging studies. In the OCD family studies and genetics literature it has been suggested that a subtype of OCD is defined by association with tic disorders (Leonard et al., 1992; Pauls et al., 1995), and phenomenological differences have been reported (George, Trimble, Ring, Sallee, & Robertson, 1993). It has also been suggested that there may be an infection-triggered, autoimmune subtype of pediatric OCD and Tourette's syndrome (TS) (Allen, Leonard, & Swedo, 1995). As to the question whether the underlying processes in OCD are similar to those in other disorders, there has been an increasing interest in the concept of "OCD spectrum disorders" (Hollander & Wong, 1995; Tynes, White, & Steketee, 1990). Particular interest has focused on comorbidity and possible etiological linkages between OCD and eating disorder (de Silva, 1993; Halmi et al., 1991; Jarry & Vaccarino 1996; Rubenstein, Altmeus, Piggott, Hess, & Murphy, 1995; Solyom, Freeman, & Miles, 1982; Thiel, Broocks, Ohlmeier, Jacoby, & Schussler, 1995). Hollander and Wong (1995) propose an inclusive model which links hypothesized subtypes of OCD to many other kinds of disorders including somatoform disorders, dissociative disorders, eating disorders, schizo-obsessive disorder, tics, neurological disorders, and impulse disorders.

On the basis of studies, the role of genetic determination of OCD also remains unclear. The standard methodology of twin/adoption studies has not been readily applicable to OCD because of its rarity. Alternatively, particularly when the prevalence of the disorder was thought to be much rarer than it now is, discovery of identical twins both of whom had OCD was thought to provide evidence of genetic determination (Woodruff & Pitts, 1964), and there have been many reports of such twins in the literature (reviewed by Carey & Gottesman, 1981; Macdonald, Murray, & Clifford, 1991; and Pauls, Raymond, & Robertson, 1991). Generally, these findings are inconclusive in the absence of control for environmental factors, standardly by comparison with discordant monozygotic twins.

In the absence of sufficient numbers of twins one or both of whom have OCD, an alternative methodology involves investigation of obsessional traits in community sample twins. Such studies have suggested heritability of a general neurosis factor. Clifford, Murray, and Fulker (1984) gave the Leyton Obsessional Inventory (LOI) and the Eysenck Personality Questionnaire (EPQ) to 419 pairs of nonclinic referred twins. Heritability for LOI trait and symptom scales were estimated as 47% and 44%, respectively and comparison with the EPQ suggested a strongly inheritable neurosis factor. This finding was consistent with studies by Young, Fenton, and Lader (1971) and Torgerson (1980). Clifford et al. (1984) also found, however, an independent obsessional trait factor relating to "incompleteness, cleanliness, and checking."

Again in the absence of a direct twin methodology for studying the genetics of OCD, an alternative, weaker approach examines incidence of the disorder in the families of individuals who have it. Family studies of relatives of OCD probands have consistently suggested rates of OCD or "subthreshold" OCD higher than population base rates, ranging between 4% and 35% (Bellodi, Sciuto, Diaferia, Ronchi, & Smeraldi, 1992; Lenane et al., 1990; Leonard et al., 1992; Riddle et al., 1990; Thomsen, 1995b). This large range reflects at least the vagueness or variable use of the notion of "subthreshold" OCD, together with the fact that the base rate of this condition in the community is unknown; furthermore, the absence of nonclinic control groups in these studies is a significant methodological weakness. Another problem is absence of control for anxiety. Two family studies which controlled for anxiety by including an anxious non-OCD group failed to find raised rates of obsessive-compulsive symptomatology in first-degree relatives (Clark & Bolton, 1985; Last, Hersien, Kazdin, Orvaskhel, & Perrin, 1991). OCD family studies by Black and his colleagues bear on both these points. Black, Noyes, Goldstein, and Blum (1992) found that the rates of anxiety disorder were higher among the relatives of the probands with OCD compared with relatives of psychiatrically normal controls, but the rate of OCD was not; though they did find higher rates of subdiagnostic threshold obsessive-compulsive symptomatology in the parents of probands with OCD than in parents of the control subjects. The findings suggested that anxiety disorder diathesis is transmitted in families with OCD but that its expression is variable, and they were interpreted as consistent with the classification of OCD as an anxiety disorder. Subsequent analysis comparing psychiatric disorders in the relatives of probands with OCD and comorbid major depression or GAD suggested that GAD may represent an alternative expression of the genetic factor(s) contributing to OCD (Black, Goldstein, Noyes, & Blum, 1995).

A different line of evidence relating to genetic factors in OCD comes from studies of the disorder in relatives of patients with tics or TS. Several studies have suggested that TS is inherited as an autosomal dominant trait (Comings, Comings, Devor, & Cloninger, 1984; Kidd & Pauls, 1982; Pauls & Leckman, 1986; Price, Kidd, Cohen, Pauls, & Leckman, 1985), and the inclusion of relatives with OCD improves the fit of the single gene solution (Pauls & Leckman, 1986). These results suggest that in TS families, OCD is part of the TS spectrum. This hypothesis is supported also by the finding that rates of obsessive-compulsive symptoms are raised in relatives of patients with TS compared with relatives of patients with TS who do not themselves have TS (Comings, 1994). This suggests that the genes for TS may also carry risk for OCD. Other studies have shown that OCD occurs at similar rates in families of TS probands whether probands have OCD or not (Eapen, Pauls, & Robertson, 1993; Pauls, Towbin, Leckman, Zahner, & Cohen, 1986.)

A further study by the Yale group (Pauls et al., 1995) takes the converse approach, examining tics and TS and obsessive-compulsive symptomatology in first degree relatives of probands with OCD and nonclinical controls. Results concerning obsessive-compulsive symptomatology replicate previous findings of higher rates in relatives, though absence of an anxiety control group is a methodological weakness as noted above. As to rates of tics and TS, there was a higher rate among relatives of OCD probands than controls (4.6% vs. 1.0%), consistent with the findings of Leonard et al. (1992). This suggests a relationship between the two disorders, and that individuals with OCD and tics are more likely to have the form of OCD related to TS. It was also found that relatives were more likely to have tics/TS if the proband did, indicating that OCD and tics/TS are not always related and suggesting that in OCD families, TS is not an alternative expression of etiology responsible for OCD. This linkage may exist, however, in TS families as indicated above. The study found that relatives of early onset OCD cases (< 18 years) were more likely to have both OCD and tics, with greatest risk in case of onset between five and nine years. This suggests that childhood onset OCD may be the more heritable form (associated with tics/TS). Finally, the Yale group study found that rates of TS/tics were higher in relatives of OCD probands with a family history of OCD compared with those without family history, suggesting a nonfamilial form of OCD. Relative methodological weaknesses of this study include its use of family history as opposed to twin methodology, the absence of an anxiety control group, and use of a clinic sample, which may increase comorbidity and severity. On this last point, two studies of early onset OCD in community cohorts have failed to find association between tics and the disorder (Douglass, Moffitt, Dar, McGee, & Silva, 1995; Flament et al., 1988).

In summary, the role of genetic determination of OCD and whether there are genetically distinct subtypes remains unclear. Macdonald, Murray, and Clifford (1991) conclude their review by proposing that studies of obsessional symptomatology in larger community twin samples are needed, and this methodology would also test the validity of the Yale group's findings and hypotheses with a relatively stronger design.

5.15.2.6 Developmental Course

Studies of the course of OCD may be divided into those conducted before, and those after, development in the late 1970s of the two main current treatments, behavior therapy and pharmacotherapy with SRIs. It would be fair to say that this time period coincided roughly with increasing precision in diagnosis and increasing sensitivity of symptom measurement. A number of earlier long-term follow-up studies using various methodologies reported reasonable recovery in something the order of half of the cases (Lewis, 1936; Pollit, 1957; Rudin, 1953), though a subsequent large study indicated a somewhat less optimistic picture, however, with only one-quarter of the patients showing much improvement over the long term (Kringlen, 1965). The more rigorous studies since the 1970s are generally of the course of the disorder under more or less controlled conditions of effective behavioral and/or pharmacological treatments, and these are discussed in Section 5.15.4.

Other aspects of the course of the disorder concern continuity of presentation. While the content of obsessions and compulsions may change within individuals over time (Rettew et al., 1992), there is, as already noted, remarkable constancy in the phenomenology of OCD through the age range from childhood to adulthood. Further, the disorder usually "runs true" in the sense that disorder substitution is not common. This applies in retrospect, considering the past history of adult cases (Zeitlin, 1986), and in prospect, considering the future long-term course of child and adolescent cases (Bolton, Luckie, & Steinberg, 1995; Leonard et al., 1993; Thomsen & Mikkelsen, 1995).

More complicated, and so far hardly addressed questions, concern precursors of the disorder. As outlined above, one kind of current model of OCD postulates that it is fundamentally a neurological disorder, and it raises the question whether there is a neurodevelopmental pathway to it. Assuming that neurological injury is not sustained after birth, the broad possibilities are that there is a genetic abnormality predisposing to the disorder, or there is an early environmental impact on the brain, *in utero*, or in the form of obstetric complications. Neural abnormalities derived in one or more of the above ways, early in development, would be in principle detectable. They may have no manifestations prior to onset, but could show up as precursors of the disorder, or, particularly in the case of genetic predisposition, as risk factors evident not only in cases but also in relatives who may or may not have the disorder. The hypothesis of a neurodevelopmental pathway would be likely to predict that early onset, in childhood and early adolescence, would be associated with more signs of abnormal neurological involvement, with being male rather than female, with poorer treatment response and prognosis, and possibly with greater familial incidence of related symptomatology.

Such evidence as there is tends to be limited or nonsupportive. There is no clear support for the prediction that early onset cases, particularly males, have poorer prognosis (Bolton et al., 1995; Leonard et al., 1993; Thomsen and Mikkelsen, 1995). In addition, as discussed above, on the basis of studies so far the role of genetic determination remains unclear. So far as the author is aware there has been only one large-scale community study which has examined precursors of OCD in a prospective longitudinal design, the study was part of the Dunedin Multidisciplinary Health and Development Study based in the province of Otago, New Zealand (Douglass et al., 1995). Douglass and her colleagues report longitudinal data from birth on individuals with OCD at age 18 in a cohort of 930 people. The one year prevalence rate of OCD at age 18 was found to be 4% ($N = 37$). The majority of OCD cases met criteria for comorbid disorder, most commonly depression, social phobia, and psychoactive substance dependence. To examine correlates and predictors of OCD, the group with OCD ($N = 37$) was compared with three other groups defined as follows: without any psychopathology ("healthy group") ($N = 590$), conduct disorder without OCD ($N = 45$), and a mixed affective/anxiety disorder group (any anxiety disorder except OCD, and/or major depression or dysthymia) ($N = 215$). No significant differences between the four groups were found on measures of a number of factors implicated by current neurological deficit models of OCD, including measures of perinatal problems/complications, tics (assessed at ages seven, nine, and 11), and various neuropsychological tests of executive functioning (at age 13). The absence of association between OCD and tics/TS in the Dunedin sample replicates the same negative result found by Flament and her colleagues in their US community sample (Flament et al., 1988). Interestingly, the Dunedin OCD group was distinguished in an apparently quite different way, by reporting more anxiety and depression in late childhood and adolescence. The OCD group reported more depressive symptomatology than any other of the three comparison groups at ages 15 and 18, and at age 11 more than the "healthy group." The OCD group also reported significantly more symptoms of anxiety at age 15 than the healthy group, and at age 18 more than any other group. The investigators concluded that depression in early adolescence was a predictor for OCD in young adulthood, and that the OCD cases at age 18 may be cases of severe, persistent, internalizing disorder.

5.15.3 CONCEPTUALIZATION AND CLINICAL FORMULATION

5.15.3.1 Multimodal Assessment

Clinical diagnosis of OCD should be primarily by clinical interview, with special attention paid to issues of differential diagnosis. Clinical mental state assessment should also screen for any comorbidity, such as depression, which may require separate therapeutic attention. A structured diagnostic interview aids reliable diagnosis and differential diagnosis of OCD, and several such interviews applicable to children are available (Silverman, 1991), such as the Diagnostic Interview Schedule for Children, 2nd edition (DISC-2.1, Fisher et al., 1993), and the Anxiety Disorders Interview Schedule for Children and Parents (ADIS-C/P, Silverman & Nelles, 1988). Care should be taken to supplement such interviews if necessary with questions needed to deliver diagnosis using the most recent editions of the standard diagnostic systems.

Following clinical diagnostic interview, scaled measures of symptomatology may be used, to make assessment of symptoms more precise, and to allow for estimation of change. For children and adolescents these include the Leyton Child Obsessional Inventory (Berg, Rapoport, & Flament, 1986). This 44-item inventory measures the number of obsessive symptoms with yes/no responses as well as degree of resistance and interference with daily activities. The inventory has reasonable test-retest reliability and discriminative validity (Berg et al., 1986), and it is sensitive to symptomatic improvement (Flament et al., 1985). The Leyton Child Obsessional Inventory has also been adapted for use in surveys (Berg, Whitaker, Davies, Flament, & Rapoport, 1988; King, Inglis, Jenkins, Myerson, & Ollendick, 1995). Currently widely used with adults is the Yale–Brown Obsessive Compulsive Scale (Y-BOCS), a semistructured interviewer-based measure with reasonable reliability, validity, and sensitivity to change (Goodman et al., 1989a, 1989b; Van Oppen, Emmelkamp, van Balkom, & van Dyck, 1995; Woody, Steketee, & Chambless, 1995). In the interview, common obsessions and compulsions are screened for, and dominant ones selected for detailed assessment including estimates of severity and interference. Evidence that Y-BOCS scores for obsessions and for compulsions in fact correspond to two factors is conflicting (Coles, Amir, & Foa, 1996; McKay, Danyko, Neziroglu, & Yaryura-Tobias, 1995), and correlation between the Y-BOCS and self-report measures of obsessive-compulsive symptomatology has been found to be relatively low (Coles et al., 1996). The Children's Yale–Brown Obsessive Compulsive Scale (CY-BOCS) consists of virtually the same items and format as the adult version, with minor wording modification for younger children (Berg, 1989; Goodman, Price, Rasmussen, Riddle, & Rapoport, unpublished).

The extent of obsessive-compulsive symptomatology can also be assessed using general observational methods such as self-monitoring and monitoring by parents or nurses (Wolff & Wolff, 1991). There has also been interest in behavioral measures of severity of some aspects of obsessive-compulsive symptomatology (Steketee, Chambless, Tran, Worden, & Gillis 1996). A number of self-report measures are available for assessing unwanted, intrusive thoughts, reviewed by Clark and Purdon (1995), though generally they have been used so far with adults rather than with children.

Apart from diagnostic and quantitative assessment of symptomatology, assessment for clinical purposes depends on the model of etiology being used and on the intended methods of treatment.

5.15.3.2 Treatment Foundation

In preparing the child or adolescent and their family for treatment much depends on the treatment which is to be used. There are currently two main treatments: behavior therapy, specifically exposure with response prevention, and pharmacotherapy, specifically using serotonin reuptake inhibitors, and the two treatments can be used in combination.

If behavior therapy is to be used, the standard method of introduction is to frame OCD as an anxiety disorder, with compulsions described as methods of reducing anxiety prompted by obsessional thoughts. Behavioral treatment, specifically occurrence of the obsessional thought (perhaps cued by exposure to an appropriate external stimulus) followed by prevention of the compulsion, can then be described as a desensitization process. In this approach to OCD, preparatory assessment in effect proceeds as for any other anxiety disorder, whether treatment is to be with the individual (Kendall et al., 1991) or the family (Bolton, 1994). This preparatory assessment would include functional analysis of the anxiety—in the case of OCD of the obsessions which express it—and of coping strategies, in this case the compulsions, though perhaps also avoidance, including the role played in these by other family members. Preparation for behavioral treatment for OCD for adults is discussed by, for example, Rachman and Hodgson (1980), and Riggs and Foa (1993), and for children/adolescents by Piacentini, Gitow, Jaffer, Graae, and Whitaker (1994) and Albano, Knox, and Barlow (1995). The model of OCD as an anxiety disorder also recommends investigation of what realistic aspects of the child's life may be a source of anxiety, what coping skills they have, and what coping skills are being modeled by the parents (Bolton, 1994). If pharmacotherapy is to be used, a view of OCD as linked to biochemical neural imbalance would be proposed.

It is possible also to prepare for treatment by framing OCD in terms of what might be called a "medical model" of the disorder. This has become popular following the neurological and in particular the "neurological deficit" models of the disorder, in which obsessions or compulsions or both are regarded as senselessly triggered by abnormal brain activity. Several OCD treatment manuals for children recommend this approach, employing terms like "hiccoughs of the brain' or "brain short circuits" (Foster, 1994; March, Mulle, & Herbel, 1994; Wever & Phillips, 1994). This is clearly compatible with exclusive use of pharmacotherapy but makes less sense when combined with behavioral therapy. Behavior therapy like any other form of psychological therapy presupposes that some aspect of the symptom is operating under psychological principles, and hence can be learned or at least unlearned.

On the other hand, it might be argued that framing OCD in terms of the "medical model" may provide a useful device in the sense of strategic therapy (Haley, 1976). In this connection it is significant that March et al. (1994) cite as a rationale for their treatment introduction a book on therapy using narrative methods (White & Epston, 1990).

5.15.4 TREATMENT

5.15.4.1 Psychosocial Treatments

As already indicated, the standard psychological treatment for OCD at any age is behavioral therapy, specifically exposure with response prevention. Exposure is to feared stimuli, and these are specifically the obsessional thoughts. This exposure may occur naturally, with the passage of time, or in contact with things in daily life, but may for treatment purposes be artificially provoked by exposure to objects of fear, such as objects thought to be contaminated. Obsessional thoughts generate anxiety, and response prevention is then a matter of not carrying out the compulsion which normally serves to reduce it. At first the person's anxiety rises, but eventually it subsides. With repetition and consolidation, the anxiety associated with not performing the compulsion, and eventually the anxiety associated with the obsessional thought itself, attenuates. In psychological theory the process is fundamentally one of extinction or relearning (Foa & Kozak, 1986; Marks & Tobena, 1990; Rachman & Hodgson, 1980).

There are many crucial principles and technical points to be observed when carrying out exposure with response prevention. They are extensively discussed in the adult literature, for example, Foa and Kozak (1986), Rachman and Hogdson (1980), and Riggs and Foa (1993). Behavioral treatment for children and adolescents with OCD follows basically the same principles as for adults, though there are obviously amendments in procedure to achieve age appropriateness, for example, in explaining treatment rationale, in encouraging engagement and motivation, and in obtaining consent and authority for treatment (Albano et al., 1995; Piacentini et al., 1994). Frequently, the child or adolescent with OCD involves one or both parents in obsessive rituals, and in these circumstances a family therapy approach may be required, with response-prevention being a matter of encouraging the parents in kind but firm refusal to join in (Bolton, Collins, & Steinberg, 1983; Lenane, 1989). Evidence has appeared that adults with OCD also commonly involve family members in rituals (Calvocoressi et al., 1995; Freshman, Amir, Katz, & Foa, 1996). This may mean that family therapy is indicated in these adult cases as well, but this conclusion is not obviously correct given the high effectiveness of individual treatment for adults. The position is probably that family therapy is useful for children with OCD not simply because the family is involved in the symptoms, but more because of issues of parent–child authority and dependency; that, it is to say, for the same reasons that it is frequently best to involve parents in their child's treatment whatever the presenting problem. This implies that for the older adolescent with OCD, individual behavioral therapy requiring their consent, involvement, motivation and effort, may be indicated more than (or at least as well as) family therapy. This kind of age-related indication for individual as opposed to family therapy has been suggested in the case of eating disorders (Russell, Szmukler, Dare, & Eisler, 1987).

Cognitive models of OCD have naturally suggested cognitive therapy approaches. On the basis of their model McFall and Wollersheim (1979) recommended rational emotive therapy (Ellis, 1962). The development of cognitive therapy for depression and anxiety by Beck and his colleagues (Beck, 1976; Beck, Emery, & Greenberg, 1985) has naturally led to applications of this to OCD. As discussed in Section 5.15.2.5, the cognitive formulations of OCD implicate assumptions and styles linked to both anxiety and depression, and accordingly cognitive therapy for OCD is based on methods already established in the treatment of affective and anxiety disorders, such as challenging negative self-appraisals or overestimation of risk or responsibility (Salkovskis & Warwick, 1985; Van Oppen & Arntz, 1994). All the above work has been with adults, and its applicability to children and younger adolescents is not yet clear. It may be expected that the more the therapeutic approach requires facility with abstract or theoretical styles of thinking the more it is likely to exceed the cognitive abilities of the younger child (Durlak, Fuhrman, & Lampman, 1991; Inhelder & Piaget, 1958). The cognitive therapy approaches used with children emphasize identification and modification of maladaptive self-talk, though in the case of treatment of anxiety specifically they include also focus on appraisal of realistic likelihoods of feared outcomes (Kendall, Kane, Howard, & Siqueland, 1989). These methods have been applied to children with OCD. Henin et al. (1996) reported treatment of two girls aged nine and 10 with OCD following cognitive behavioral principles closely modeled on the methods developed by Kendall and his co-workers for treatment of anxiety in children; in the first phase of treatment the child was presented with ways of coping with situations which habitually triggered obsessive-compulsive symptoms, with use of strategies such as modeling and role-play; once the skills were mastered, exposure and response-prevention were implemented.

The kinds of case in which exposure with response-prevention can most readily be used are those in which there are readily accessible behavioral compulsions in response to obsessions. The technique does not apply in cases where the person has obsessions alone, without compulsive responses to prevent. These cases are, however, rare (Foa & Kozak, 1995). But the technique is also difficult where the compulsive responses to obsessions are themselves mental, because the therapist has no straightforward way of helping the patient stop what they are doing. Cases of mental ritualizing are not so rare (Foa & Kozak, 1995). Both kinds of case—obsessions alone, and where compulsions are predominantly mental—can be brought under the heading of obsessive-compulsive "ruminations." Treatment approaches include behavioral methods such as habituation and thought-stopping (Foa, Steketee, & Ozarow, 1985; Rachman, 1985) as well as the cognitive approaches referred to above.

Another kind of presentation of OCD which requires methods other than straightforward exposure with response-prevention is so-called primary obsessional slowness, described by Rachman (1974). Its status as a separate syndrome is questionable, however, and a linked point is that the indicated treatment—prompting, pacing, and shaping—can be construed as a form of response-prevention, since in effect it prevents the patient from maintaining desired order or exactness (Veale, 1993). In general, notwithstanding the variety of obsessive-compulsive symptomatology and the corresponding need for flexibility and innovation in behavioral treatment approaches, all or most of these approaches can plausibly be regarded as variations on the theme of response-prevention, for example, the treatment of hoarding compulsions by encouraging the patient to throw away unnecessary hoarded items (Ball, Baer, & Otto, 1996; Tallis & de Silva, 1992).

5.15.4.2 Pharmacological Treatments

As noted in Section 5.15.2.5, the only drugs shown so far in group studies of various designs to be effective in the treatment of OCD are the serotonin reuptake inhibitors (Piccinelli et al., 1995; Stein et al., 1995). They are effective not only in adults (Montgomery, 1994) but also in children and adolescents with OCD (DeVane & Sallee, 1996; DeVeaugh-Geiss et al., 1992; Flament et al., 1985; Geller, Biederman, Reed, Spencer, & Wilens, 1995; Leonard et al., 1989; Riddle et al., 1992). In the case of OCD, as for other disorders, pharmacological treatment of children and adolescents should be accompanied by attention to social and family factors (Rapoport, Leonard, Swedo, & Lenane, 1993). In the context of the demonstrated effectiveness of SRIs for OCD, much remains unclear about their mode of action, including the nature of any abnormalities in the serotonergic system of patients prior to treatment, as well as the links between serotonergic activity and psychological functions (Goodman, Price, Woods, & Charney, 1991; Hoehn-Saric, McLeod, Zimmerli, & Hipsley, 1993; Insel & Winslow, 1992; Rauch & Jenike, 1993).

5.15.4.3 Effectiveness of Treatments

Effectiveness of behavior therapy in approximately 60–80% of cases has been shown in a number of studies of adults (Marks, Hodgson, & Rachman, 1975; Rachman & Hodgson, 1980), as has effectiveness of SRIs (Clomipramine Collaborative Study Group, 1991; Fineberg, Bullock, Montgomery, & Montgomery, 1992), and of combinations of the two treatments (Cox, Swinson, Morrison, & Lee, 1993; Marks, Stern, Mawson, Cobb, & McDonald, 1980; Rachman & Hodgson, 1980; Stanley & Turner, 1995). Treatment gains following behavior therapy in adulthood have been shown to maintain in the medium- to long-term (O'Sullivan & Marks, 1990; O'Sullivan, Noshirvani, Marks, Monteior, & Lelliott, 1991), while long-term preservation of gains under pharmacotherapy may require maintenance dosage for several years (Fineberg, Bullock, Montgomery, & Montgomery, 1992; Stanley & Turner, 1995).

While behavior therapy for OCD is highly effective for most people who participate, about 25–30% of patients suitable for this form of treatment do not comply with it (McDonald, Marks, & Blizard, 1988). Among those who do stay in treatment, up to 80% respond well as noted above, but conversely 20% or more do not. In sum, then, about 40–50% of referred people with OCD are not helped by behavior therapy, and it is important to bear this in mind alongside the impressive figures for its effectiveness. Considerable effort has gone into identifying factors associated with poor response to behavioral treatment in adults. These may include over-valued ideation, comorbid personality disorder, and depression, though these and other possibilities have not as yet been consistently confirmed (Basoglu, Lax, Kasvikis, & Marks, 1988; Buchanan, Ko, & Marks, 1996; Castel et al., 1994; Fals-Stewart & Lucente, 1993; Foa, 1979; Foa, Kozak, Steketee, & McCarthy, 1992; Keijsers, Hoogduin, & Schaap, 1994; O'Sullivan et al., 1991; Reich & Vasile, 1993). The causes of nonacceptance of behavioral treatment have been relatively less explored, but low motivation is apparently involved, both in adults (Hansen, Hoogduin, Schaap, & de Haan, 1992), and in children and adolescents, for example, in the form of comorbid oppositional defiance (Bolton & Turner, 1984; Wever & Rey, in press).

Motivation in the form of determination to change and belief in self-efficacy may be a crucial factor mediating both treatment compliance and effectiveness in OCD. Cognitive techniques have been used with adults to try to enhance motivation for and engagement in behavior therapy (Salkovskis & Warwick, 1985; Tallis, 1995). It is interesting to note in this connection that the two approaches to behavioral treatment for children and adolescents with OCD referred to earlier (March et al., 1994; Wever & Phillips, 1994), as well as framing OCD in terms of the medical model, also both make liberal use of methods reminiscent of treating habit disorders such as smoking where motivation for change is crucial. Such methods typically involve acknowledging the habit as bad, and emphasizing that the person, not the behavior, is in charge. The whole problem of motivation and the person's attitude to their OCD has received relatively little attention so far in the psychological theory of the disorder. A sophisticated approach would be required, such as the highly influential model of motivation for change constructed by Prochaska and DiClemente which has been applied to treatment seeking and compliance including in relation to habitual and addictive behaviors (Prochaska & DiClemente, 1982; Prochaska, DiClemente, & Norcross, 1992).

As noted in Section 5.15.4.1, obsessional ruminations can be treated by behavioral methods such as thought stopping and habituation and by cognitive approaches such as modification of abnormal risk assessment. They are notoriously difficult to treat, however, and reported results using such methods are mixed (Arts, Hoogduin, Schaap, & de Haan, 1993; Foa et al., 1985; Rachman, 1985; Salkovskis & Westbrook, 1989).

Initial case reports of cognitive therapy for OCD in adults tended to be uncontrolled and inconclusive (James & Blackburn, 1995), but several controlled studies have shown cognitive methods to be at least as effective as exposure plus response prevention. In comparisons with rational emotive therapy, Emmelkamp and his co-workers found that the two had similar effects, with no incremental effect when combined (Emmelkamp & Beens, 1991; Emmelkamp, Visser, & Hoekstra, 1988). Van Oppen et al. (1995) compared cognitive therapy with exposure and response prevention. The cognitive therapy was based on the methods of Beck (1976) and Salkovskis (1985) and focused mainly on estimation of catastrophic risk and of personal responsibility. Seventy-one adult patients were randomly assigned to one of the two treatment conditions, and seven subsequently dropped out of each. Both treatments led to significant improvement, with more participants rated as "recovered" in the cognitive therapy group. It has been also suggested that cognitive therapy techniques might be particularly useful, and certainly worth trying, in cases of failure of behavioral treatment (Salkovskis & Warwick, 1985). As to application to children, Henin et al. (1996) have reported cognitive-behavioral treatment of two children with OCD, as already noted (Section 5.15.4.1), and the outcome was successful in both cases. The role of cognitive change in mediating behavioral change during cognitive therapy, with adults or children, is not yet clear, and indeed the same question arises in the case of behavior therapy (Durlak et al., 1991; Ladouceur, Rheaume, & Leger 1996; Van Oppen, Emmelkamp, et al., 1995).

The treatment of obsessional slowness involving prompting, shaping, and pacing is generally effective while the therapist is participating, but generalization and maintenance outside of sessions is poor (Clark, Sugrim, & Bolton, 1982; Veale, 1993).

Returning to the main treatments currently in use, exposure with response prevention and medication with SRIs, broadly similar results have been found for children and adolescents with OCD as for adults. Positive, though generally partial, response to SRIs has been found in the majority of young patients with OCD, though as for adults there tends to be relapse if medication is withdrawn (DeVane & Sallee, 1996; DeVeaugh-Geiss et al., 1992; Flament et al., 1985; Geller et al., 1995; Leonard et al., 1989; Rasmussen, Eisen, & Pato, 1993; Riddle et al., 1992). There is also usually a good response to behavior therapy in this age group. An early study of 15 adolescents treated mainly by exposure with response prevention found complete or near complete symptom relief in 87% of cases (Bolton et al., 1983). Similar results have been obtained in two studies using well-defined behavior therapy programs combined with pharmacological (SRI) treatment, with significant improvement in approximately 80% ($N = 14$) (March et al., 1994) and 68%

($N = 57$) (Wever & Rey, in press) of cases under these combined treatments.

The question of the course of OCD presenting in childhood and adolescence, and the long term effectiveness of treatments, is important clinically and theoretically. Early follow-up studies of clinically referred children and adolescents with OCD indicated poor medium- to long-term outcome. Warren (1965) followed up 15 young people aged 19–24 years who had been admitted to hospital with obsessive-compulsive states when aged 12–17 years. No treatment was specified except for psychosurgery in one case. Five of the 15 young people still had severe obsessional symptomatology at follow up, and a further four were still handicapped by obsessional symptoms. Four of the 15 tended to develop mild symptoms under stress, and the remaining two were considered completely recovered. Hollingsworth, Tanguay, Grossman, and Pabst (1980) evaluated 10 of 17 pediatric outpatients and inpatients with severe obsessional neurosis treated by intensive psychotherapy in all cases, one-and-a-half to 14 years later. Seven of the 10 cases reported continuation of obsessive-compulsive behavior though at less than pretreatment levels.

The findings from these earlier follow-up studies of reasonable recovery in a third or less of cases of pediatric OCD is comparable with other findings. In the first of a pair of studies from the National Institute of Mental Health (NIMH), Flament and her colleagues followed up 27 children and adolescents assessed as having OCD at NIMH between 1977 and 1983, between two and seven (mean 4.4) years later and at age 13–24 (mean 18.8) years (Flament et al., 1990). Of the 27 subjects, 17 (68%) still qualified for diagnosis of OCD at follow-up. Treatment during the follow-up period was described as diverse, sparse, and uncontrolled. A somewhat better prognosis was found in a Danish cohort of 23 children and adolescents followed up for between 18 months and five years after treatment which did not involve a "structured treatment program" but included use of SRIs in about 25% of cases and behavior therapy in all; about 50% of cases still qualified for diagnosis at follow-up (Thomsen & Mikkelsen, 1995). A similar recovery rate in a community sample of adolescents with OCD has been observed over a two-year period (Berg et al., 1989). Leonard and colleagues followed up a second cohort of 54 children and adolescents with OCD seen at NIMH between 1984 and 1988, between two and seven (mean 3.4) years later (Leonard et al., 1993). At follow-up 43% still qualified for diagnosis of OCD. Treatment during the follow-up period was active, in contrast to the cohort seen by Flament and her colleagues, and included medication in nearly all cases and behavior therapy in a third. The predicted difference in outcome in the two NIMH cohorts was found; improvement to below diagnostic threshold was found in 57% of cases in the Leonard et al. sample, as opposed to 32% of cases in the Flament et al. sample.

Similar results in a smaller cohort over a longer time period were reported by Bolton et al. (1995, 1996). Fourteen young adults treated for the disorder in adolescence, mainly with behavior therapy and family therapy, were followed up between nine and 14 years later: six (43%) were found to satisfy *DSM-III-R* criteria for OCD at long-term follow-up, while eight (57%) were not. Sustained recovery from OCD was associated with normal levels of social functioning, consistent with the pattern found in Thomsen's Danish sample (Thomsen, 1995a). Recovered participants were not currently taking medication, a finding which contrasted with the report of Leonard and her colleagues that, in their sample, high proportions, up to 80%, of various groups of participants who no longer met diagnostic criteria for OCD continued to receive SRI medication. One possibility is that effective behavior therapy during adolescence may obviate the need for long-term maintenance pharmacotherapy.

5.15.5 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

It would be fair to say that the enormous research effort which has gone into understanding OCD since the early 1980s has raised as many questions as have been answered about the nature and etiology of the disorder. There is an apparent contrast between the traditional view of OCD as fundamentally an anxiety disorder and what has emerged as a new orthodoxy, that it is fundamentally a motor disorder caused by some form of neurological lesion. No one kind of evidence, let alone a single test, could ever settle this kind of issue, but evidence from a variety of methodologies—as reviewed in this chapter—will continue to accrue until a coherent pattern or number of patterns emerge. The various methodologies exist at several levels, from the cultural to the neurological, and the questions they address are also important in their own right. Key outstanding issues include the nature of and interaction between the psychological processes implicated in the disorder, such as anxiety, magical belief, exaggerated sense of responsibility, and dysfunctional memory. There are outstanding issues concerning the neurological basis of the disorder, such as concerning the role of serotonin, and the site of structural lesions in some cases. Important questions in the genetics of the disorder remain unclear in the absence of a large community twin study.

A substantial question in the background, interweaving with etiological issues, is the extent to which OCD as understood in the 1990s, is in fact a well-defined psychobiological entity. It may turn out that significant subtypes exist within OCD and/or that causal pathways criss-cross OCD and associated or related psychopathologies. In the present state of theoretical uncertainty this is a particularly tempting line of enquiry, although as yet attempts to subcategorize OCD in useful, predictive ways have so far been speculative. One possibility specifically interesting in relation to childhood presentations of the disorder is whether there a distinctive neurodevelopmental pathway to and subtype of the disorder, and future research will no doubt cast light on this issue.

From the treatment point of view both pharmacotherapy with SRIs and behavior therapy using exposure with response-prevention have both been shown to be highly effective for many patients in the short- and long-term. Outstanding issues include how to improve outcome in treatment resistant cases, and how to manage relapse effectively. Cognitive therapy may play an increasingly important role in these respects.

5.15.6 SUMMARY

OCD is a relatively common disorder in children and young people, with current estimates suggesting a life-time prevalence by adolescence of around 2%. Comorbidity with other disorders is common, including depression, other anxiety disorders, and tics. Psychological theories of OCD mainly involve variations on the themes of unresolved anxiety in combination with active but maladaptive anxiety reduction, and they can be linked in one direction to phylogenesis in terms of displacement activities and in the other to ontogenesis in terms of styles of cognitive appraisal. An alternative view is that OCD may be a neurological motor disorder, with obsessional thought being like confabulation. Neuro-imaging findings on the neuroanatomical basis of the disorder are fairly consistent, and the specific effectiveness of SRIs indicates a relatively circumscribed neurochemical basis. On the basis of studies so far the role of genetic determination remains unclear. OCD often begins in childhood or adolescence, and a variety of useful assessment measures have been developed for these early onset cases. Without current, effective treatments the disorder can run a chronic course. Currently indicated treatments are behavior therapy, specifically exposure therapy with response-prevention, and pharmacotherapy with SRIs. Pharmacotherapy is less time-consuming but behavior therapy may protect more against relapse. Cognitive therapy for OCD has been shown to be as effective as behavior therapy with adults, and is just beginning to be applied with children.

5.16.1 INTRODUCTION

The period from the 1970s to the 1990s has shown that children react to life-threatening stressors with various forms of distress, anxiety, fears, depression, and bereavement reactions, as well as post-traumatic stress disorder (PTSD). The form of PTSD varies somewhat according to the age of the child and, sadly, the internal distress often goes unrecognized for long periods by parents and teachers. Indeed, one reason for the initial doubt whether PTSD occurred in children at all was that few investigators had asked children directly how they were affected.

Although post-traumatic stress reactions have been known to occur for centuries, our understanding of people's reactions to life-threatening experiences have been advanced in the aftermath of the major wars of the twentieth century. It was not until the persisting problems of Vietnam veterans were better documented that it was realized that three major groups of symptoms exist: distressing recurring recollections of traumatic events, avoidance of trauma-related stimuli, and a range of symptoms associated with increased arousal. These came to be known as PTSD (American Psychiatric Association, 1980).

Since its inclusion in the third edition of the *Diagnostic and statistical manual for mental disorders* (*DSM-III*) (American Psychiatric Association, 1980), PTSD has been the subject of much debate regarding its validity, etiology, placement among the anxiety disorders, and even its status as a "true" mental disorder (Yehuda & McFarlane, 1995). Nowhere has the controversy over the validity of PTSD as a diagnostic entity been greater than in the child trauma literature (Pynoos, 1994). This is due in part to the observation that the reactions commonly observed in traumatized children are so much wider than the narrow confines described under PTSD in the various revisions of the *DSM* and the *International classification of diseases* (*ICD-10*) (World Health Organization, 1992; Yule, 1994). Moreover, some have suggested that children are so resilient that even when they experience an acutely stressful event, they develop, at worst, some sort of transient reaction disorder (Garmezy, 1984; Garmezy & Rutter, 1985).

Despite the controversy, PTSD is a very useful framework for describing and understanding childrens' reactions to a wide range of life-threatening experiences. Research since the mid-1970s suggests that significant and often chronic symptoms of PTSD are found among children following exposure to war (Arroyo & Eth, 1985; Kinzie, Sack, Angell, Manson, & Rath, 1986; Saigh, 1989a, 1991), natural disaster (Earls, Smith, Reich, & Young, 1988; Frederick, 1985a; Galante & Foa, 1986; Goenjian; 1993; Green et al., 1991; Lonigan, Shannon, Finch, Daugherty, & Saylor, 1991; McFarlane, 1987; Milne, 1977; Newman, 1976), manmade and transportation disasters (Handford et al., 1986; Parry-Jones, 1996; Terr, 1979, 1983; Yule; 1992), violence and violent crime (Malmquist, 1986; Pynoos & Eth, 1988; Schwarz & Kowalski, 1991), sexual abuse (Goodwin, 1988; McLeer, Deblinger, Henry, & Orvaschel, 1992; Wolfe, Gentile, & Wolfe; 1989), and serious medical illness (Nir, 1984; Stuber, Nader, Yashuda, Pynoos, & Cohen, 1991). Still, there remain considerable gaps in our understanding of the disorder in children, particularly in regard to its developmental, neurobiological, and physiological manifestations across those of various ages and abilities.

In this chapter, the literature on childhood PTSD is highlighted and reviewed with a view to increasing the reader's understanding of the phenomenology, assessment, and treatment of the disorder. However, an exhaustive review of the issues pertinent to the manifestation of PTSD following specific types of traumas (e.g., war, torture, natural disaster, and sexual assault) is beyond the scope of this chapter. The reader should be aware that significant differences exist in the clinical presentation and treatment of children with specific trauma histories.

5.16.2 PTSD

5.16.2.1 Phenomenology of Stress Reactions in Children and Adolescents

From their experience working with child and adolescent survivors of the "Herald of Free Enterprise" car ferry sinking (Yule & Williams, 1990), the sinking of the cruise ship, "Jupiter" (Yule, 1992; Yule, Udwin, & Murdoch, 1990), war-affected children of the former Yugoslavia (Smith, Yule, Perrin, & Schwarz, 1996), and childhood survivors of serious road traffic accidents in Britain (Perrin, Yule, & Smith, 1996b; Yule, Perrin, & Smith, 1996), Yule and colleagues have noted a number of reactions that are common in children exposed to traumatic events.

Most children are troubled by repetitive, intrusive thoughts about the trauma. Such thoughts can occur at any time, but particularly when the children are otherwise quiet, as when they are trying to fall asleep. At other times, the thoughts and vivid recollections are triggered off by reminders in their environment. Sleep disturbances are very common, particularly within the first few weeks of the event. Fears of the dark, bad dreams, nightmares, and waking through the sleep cycle are widespread. Separation difficulties are frequent, even among teenagers. For the first few days, children may not want to let their parents out of their sight, even reverting to sleeping in the parents' bed. Many children become much more irritable and angry with parents and peers alike.

Although child survivors often experience a pressure to talk about their experiences, paradoxically they also find it very difficult to talk with parents and peers. Often they do not want to upset the adults, and so parents may not be aware of the full extent of their childrens' suffering. Peers may hold back from asking what happened lest they upset the child further; the survivor often takes this as a subtle form of rejection.

Children report a number of cognitive changes. Many experience difficulties in concentration, especially in school work. Others report memory problems, both in mastering new material and in remembering previously learned skills such as reading music. They become very alert to danger in their environment, being adversely affected by reports of other related traumatic events. Survivors often learn that life is quite fragile, particularly if they sustained any permanent form of injury or witnessed the death of another. This can lead to a sense of a foreshortened future, often expressed as a loss of thoughts about the future. Life priorities frequently change in response to trauma, with some feeling that they should live each day to the full and not plan for the future. Others realize that they have been overconcerned with materialistic or petty matters and resolve to rethink their values, frequently taking on the image of themselves as a helper to others. Such ways of thinking may reflect a change in the child's "assumptive world" (cf., Janoff-Bulman, 1992).

Not surprisingly, many children develop fears associated with specific aspects of the traumatic event(s), with phobic levels of avoidance to trauma-related stimuli and reminders. Many experience "survivor guilt" about others dying or being seriously injured, or think they should have done more to help others to survive. Adolescent survivors report significantly high levels of depression, some becoming clinically depressed, having suicidal thoughts, and taking overdoses in the year after a disaster. A significant number become very anxious after the trauma, although the appearance of panic attacks is sometimes considerably delayed.

In summary, children and adolescents surviving a life threatening trauma show a wide range of symptoms which tend to cluster around symptoms of re-experiencing, avoidance of trauma-related cues and emotions, and increased physiological arousal. There may be considerable comorbidity with depression, generalized anxiety, or pathological grief reactions as well.

5.16.2.1.1 Age and gender-related effects of trauma on children

While there have been relatively few systematic studies examining the impact of trauma at different stages of development, there do appear to be important age-related differences in the expression of PTSD (see Lyons, 1987 and Terr, 1991 for reviews). Schwarz and Perry (1994) have suggested that infants and very young children are more sensitive to emotional states and behavior of parental caregivers than to assessments of danger. As such, a trauma to either the child or primary caregiver may result in global dysfunction, apathy and failure to thrive, excessive crying, eating and sleeping, psychophysiological lability, and overstimulation (Schwarz & Perry, 1994).

Among toddlers and preschool children, high levels of dependency (clinginess) and separation anxiety are frequent, with regressive behaviors such as bed-wetting, baby-talk, and thumb-sucking also observed. Diarrhea and frequent somatic complaints may be noted, as well as irritability, sleep problems, and fearfulness. Some children may show delays in cognitive and language development (Law & Conway, 1992) and mutism (Eth & Pynoos, 1985). Re-enactment of the trauma through play and difficulty with verbal descriptions of the trauma are common. Many preschool children show a loss of interest in activities and hobbies that previously gave them pleasure. Although some have suggested that emotional numbing may be rare in this age group, this may be an artifact of the difficulty researchers have found eliciting evidence of such symptoms in young children (Frederick, 1985a).

In reviewing data from the Buffalo Creek Disaster, Green et al. (1991) noted that preschoolers had fewer PTSD symptoms overall, and in particular avoidance symptoms, than older children. They hypothesized that it may be more difficult to observe avoidant symptoms (as well as dissociation and emotional numbing) in this age group. Consistent with Schwarz and Perry's hypothesis (1994), the preschool child's perception of the dangerousness of the trauma (i.e., life threat) was not correlated with PTSD symptoms, while life threat was positively associated with PTSD symptoms in school-aged children and adolescents (Green et al.).

Relative to preschool children, those of school age may show an increased frequency of trauma-related nightmares, preoccupation with the trauma, vacillation between withdrawal and aggressive outbursts, and avoidant behaviors (Lyons, 1987). Somatic complaints may be less frequent, and this may be related to an increased verbal ability to describe the trauma. Children of this age can begin to appreciate the irreversibility of tragic events and may exhibit more overt signs of depressed mood and hopelessness.

Given that concentration difficulties are characteristic of PTSD (American Psychiatric Association, 1994), one might expect that children's school work would suffer after a traumatic event. However, Martin and Little (1986) found no differences in scholastic attainment across three groups of 9–10 year-old children with varying degrees of exposure, two months after a tornado. The authors speculated that this may have been the result of the community pulling together in the face of the trauma, and because children were relocated to new schools where teachers were instructed to discuss the children's experiences of the tornado (Martin & Little, 1986).

Among adolescents, there is an increased frequency of adult-like PTSD symptoms, problems with compliance and withdrawal, aggressiveness, substance abuse, and increased feelings of guilt. Problems of identity, eating, self-mutilation, and personality may also be noted (Schwarz & Perry, 1994). In contrast to younger children, there is generally an absence of traumatic play. In addition, there is clearer evidence of impaired academic performance post-trauma in adolescents. Girls who survived the sinking of the Jupiter who were above average in performance during the three years before the sinking, plummeted significantly to merely average levels one year after the disaster (Yule, 1992). Two years after the accident, the 16-year old survivors still performed less well in national school exams, although the difference with pretrauma performance was no longer as marked (Tsui, 1990).

With respect to gender, girls consistently score higher across measures of post-traumatic distress, anxiety, and depression than boys in a number of studies, including children exposed to a shipping disaster (Yule, 1992), a hurricane (Lonigan et al., 1991), flood (Green et al., 1991), an earthquake (Pynoos et al., 1993), and war in former Yugoslavia (Smith et al., 1996). One study (Burke, Moccia, Borus, & Burns, 1986) did find boys' distress to be higher than girls five months after a flood; however, this pattern reversed at a follow-up assessment five months later.

5.16.2.1.2 Cultural factors in the expression of PTSD

There has been some debate over the appropriateness of using PTSD to characterize the traumatic reactions of children from non-Western countries (see Eisenberg, 1996 and Summerfield, 1996). Unfortunately, there are few empirical investigations from which to draw firm conclusions. Studies of children's fears more generally suggest that the most common fears are the same across different countries and cultures (see Fonesca, Yule, & Erol, 1994 for a review). Indeed, the current literature suggests that there are remarkably few psychiatric disorders which are culture-specific (Leff & Bhugura, 1993). However, the question remains whether the traumatic reactions observed in children across different cultures are more similar than different and when such reactions should be considered abnormal or pathological.

Working with a core set of self-report instruments to screen children in exceptionally difficult circumstances, Yule, Pynoos, and others have begun to study this issue more directly. The Impact of Events Scale (IES) (Horowitz, Wilner, & Alvarez, 1979) has been modified for use with children in both civilian and war situations. Examining data from studies of war affected children in Iraq, Kuwait, and the former Yugoslavia, it was found that the IES factor structures obtained from children in Iraq (Dyregrov & Yule, 1995) and Yugoslavia (Perrin, Smith, Schwartz, & Yule 1996a) were identical to that obtained from British children who had survived the Jupiter shipping disaster. In addition, the number of war traumas reported by children from Yugoslavia was positively correlated with levels of distress on translated versions of the IES, Birleson Depression Inventory (Birleson, 1981), and Revised Children's Manifest Anxiety Scale (Reynolds & Richmond, 1978) (Perrin et al., 1996a). Moreover, this battery of instruments proved sensitive to pre–post-treatment changes in Yugoslavian children who participated in cognitive behavioral treatment (Dyregrov & Yule, 1995).

Finally, Pynoos and colleagues observed that child survivors of the Armenian earthquake not only show the classic symptoms of PTSD as measured with structured interview and self-report questionnaires, but also show greatly increased salivary cortisol levels and disturbed basal heart rates (Pynoos et al., 1993). The presence of these physiological markers of hyperarousal, which are presumably less affected by cultural influences than scores on translated self-report inventories, lends considerable support to the argument for PTSD symptoms manifesting across cultures. Of course, assessments and interventions should be culture-sensitive. As suggested by Parry-Jones (1996), labeling clinically significant stress reactions need not be stigmatizing and indeed may ensure that appropriate treatment services are offered.

5.16.2.2 Diagnostic Features

PTSD first entered the diagnostic nomenclature with its appearance in *DSM-III* (American

Psychiatric Association, 1980), appearing in the anxiety disorders section. The criteria were based largely on a then emerging body of research with adult trauma survivors, particularly combat veterans. Under *DSM-III*, PTSD was characterized by: (i) the experience of a traumatic event outside the range of usual human experience; (ii) distressing and recurring recollections of the traumatic event; (iii) numbing of responsiveness and/or reduced involvement with the external world; and (iv) at least two of a variety of symptoms including survivor guilt, sleep disturbances, hyperarousal, avoidance of trauma-related stimuli, and impaired concentration (Lyons, 1987). However, few and vague descriptions of the manifestations of PTSD in children of different ages were noted, owing to the paucity of methodologically sound research available on children's reactions to traumatic events.

The third revised edition of the *DSM* (*DSM-III-R*) (American Psychiatric Association, 1987) was the first to note the occurrence of PTSD in children but the specific criteria remained largely unchanged. Rather, the revisions involved a reorganization of the existing symptoms under re-experiencing, numbing and avoidance, and increased arousal categories (Lyons, 1987). However, there were two exceptions. First, a "sense of a foreshortened future" was added based on research with the children of the Chowchilla bus kidnaping (Lyons, 1987). Second, and unfortunately, "survival guilt" was removed, although this symptom is found frequently in both children and adults presenting with PTSD (Yule, 1994).

Under *DSM-IV* (American Psychiatric Association, 1994), the requirements for meeting a diagnosis of PTSD have changed considerably from its predecessors. The *DSM-IV* criteria for PTSD are as follows:

(i) The person has been exposed to a traumatic event in which both of the following have been present:

(a) The person has experienced, witnessed, or been confronted with an event or events that involve actual or threatened death or serious injury, or a threat to the physical integrity of oneself or others.

(b) The person's response involved intense fear, helplessness, or horror. Note: In children, it may be expressed by disorganized or agitated behavior.

(ii) The traumatic event is persistently re-experienced in at least one of the following ways:

(a) Recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions. Note: In young children, repetitive play may occur in which themes or aspects of the trauma are expressed.

(b) Recurrent distressing dreams of the event. Note: In children, there may be frightening dreams without recognizable content.

(c) Acting or feeling as if the traumatic event were recurring (includes a sense of reliving the experience, illusions, hallucinations, and dissociative flashback episodes, including those that occur upon awakening or when intoxicated). Note: In young children, trauma specific re-enactment may occur.

(d) Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.

(e) Physiological reactivity upon exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event.

(iii) Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before the trauma), as indicated by at least three of the following:

(a) Efforts to avoid thoughts, feelings, or conversations associated with the trauma.

(b) Efforts to avoid activities, places, or people that arouse recollections of the trauma.

(c) Inability to recall an important aspect of the trauma.

(d) Markedly diminished interest or participation in significant activities.

(e) Feelings of detachment or estrangement from others.

(f) Restricted range of affect (e.g., unable to have loving feelings).

(g) Sense of a foreshortened future (e.g., does not expect to have a career, marriage, children, or a normal life span).

(iv) Persistent symptoms of increased arousal (not present before the trauma), as indicated by at least two of the following:

(a) Difficulty falling or staying asleep.

(b) Irritability or outbursts of anger.

(c) Difficulty concentrating.

(d) Hypervigilance.

(e) Exaggerated startle response.

(v) Duration of the disturbance (symptoms in (ii), (iii), (iv) are more than one month)

(vi) The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Specify if:

Acute: If duration of symptoms is less than three months.

Chronic: If duration of symptoms is three months or more.

With delayed onset: Onset of symptoms at least six months after the stressor.

In particular, criterion (i) has been clarified greatly such that more emphasis is placed on the threatening nature of the traumatic event to the person rather than it being outside the range of normal human experience. Also, the ways in which several symptoms manifest themselves in children are defined more clearly. Similar to *DSM-III*, *DSM-IV* notes that children's re-experiencing can be expressed as repetitive and trauma-thematic play, nightmares with/without traumatic content, and re-enactment of the trauma. Interestingly, the fourth edition no longer specifies "loss of previously acquired developmental skills" as a potential avoidance item and this may affect case identification (Ribbe, Lipovsky, & Freedy, 1995).

The inclusion of PTSD among the anxiety disorders in the *DSM* has led to considerable controversy among trauma and anxiety researchers alike (cf., Pynoos, 1994; Saigh, 1989b). While characterized by predominant symptoms of fear, avoidance, and hyperarousal, PTSD differs from the other anxiety disorders in that it requires a "putative" event (i.e., the trauma). Thus, there is an assumed causal relationship between an external event and the onset of the disorder. In this way, PTSD more resembles an adjustment disorder. Indeed, the notion that PTSD is "a normal reaction to an abnormal situation" has led some to question whether it is in fact a psychiatric disorder at all (cf., O'Donohue & Elliot; 1992).

PTSD also differs from the anxiety disorders in other important ways. Foa, Steketee, & Olasov-Rothbaum (1989) observed that trauma giving rise to PTSD violated more of the survivor's safety assumptions than did events leading to other forms of anxiety. Also, there was a much greater likelihood of fear generalization and subjective re-experiencing of the anxiety-eliciting event in PTSD than other anxiety disorders (Foa et al., 1989). Some have suggested that it is this internal, subjective experience of the traumatic event that most seems to set PTSD apart from the other anxiety disorders (Jones & Barlow, 1992; Keppel-Benson & Ollendick; 1993). Others have argued that it is the psychogenic amnesia and numbing of general responsiveness which separate PTSD clearly from anxiety, and places it more appropriately among the dissociative disorders. Still others (Pitman et al., 1990) have pointed out that exposure to trauma cues in combat veterans was just as likely to produce responses of anger and grief than fear, and thus PTSD might arguably be placed among the affective disorders.

To add to the controversy, it is widely recognized that the PTSD criteria, as currently defined, poorly reflect the wide variety of major stress responses reported in the literature. Thus, it can be argued that many seriously traumatized individuals might not meet criteria for PTSD under the *DSM*. As mentioned above, "survivor guilt" and grief reactions have largely been lost in each subsequent revision since *DSM-III*. Nor is there any mention in *DSM-IV* of the profound sexual, interpersonal, and identity problems often found in survivors of repeated sexual assault.

This has led some to ask whether a spectrum of disorders, including PTSD, should be delineated to capture more accurately the range of traumatic responses seen by clinicians and researchers (Kolb, 1988). In this regard, some have argued for an additional grouping to be recognized—Disorders of Extreme Stress Not Otherwise Specified (DESNOS) (Herman, 1992). The distinction between PTSD and DESNOS is similar to the distinction drawn by Terr (1991) between Type I (characterized by intrusive recollections) and Type II (characterized by denial, numbing, and dissociation) PTSD in children (Yule, 1994).

PTSD is also included in the tenth edition of the *International classification of diseases* (*ICD-10*) (World Health Organization, 1992). However, its inclusion among the adjustment disorders has avoided the controversy surrounding PTSD in the *DSM*. According to *ICD-10*: "[PTSD] arises as a delayed or protracted response to a stressful event or situation ... of an exceptionally threatening or catastrophic nature, which is likely to cause pervasive distress in almost anyone (e.g., natural or man made disaster, combat, serious accident, witnessing the violent death of others, or being a victim of torture, terrorism, rape, or other crime)" (World Health Organization, 1992, p. 147).

ICD-10 lists symptoms similar to those in *DSM-III-R*, but emphasizes the presence of repetitive, intrusive memories characteristic of the disorder rather than the avoidance symptoms. Specifically, the manual states: "A conspicuous emotional detachment, numbing of feeling, and avoidance of stimuli that might arouse recollections of the trauma are often present but *are not essential* for the diagnosis. The autonomic disturbances, mood disorder, and behavioral abnormalities are all contributory to the diagnosis but not of prime importance" (World Health Organization, 1992, p. 148). It is also worth noting that the *ICD-10* states that PTSD should only be diagnosed when it arises within six months of a major trauma, whereas *DSM-IV* allows the diagnosis to be made when onset occurs after six months post-trauma (as noted by the specification Delayed Onset (American Psychiatric Association, 1994).

5.16.2.2.1 Prevalence

Epidemiological investigations of adults in the general population estimate a lifetime prevalence of PTSD between 1 and 9.2% (see Fairbank, Schlenger, Saigh, & Davidson, 1995 for a review of epidemiological investigations of PTSD). The prevalence of PTSD among children in the community is unknown. There have been no epidemiological investigations of the disorder to date. However, there have been several studies of PTSD in children exposed to war, natural disaster, violent crime, and sexual abuse ("at-risk" groups).

Prevalence rates from studies of at-risk children vary widely (from 0 to 100%). This extreme variability is consistent with findings from studies of at-risk adults (Fairbank et al., 1995), and is reflected in the estimates given for at-risk groups in *DSM-IV* (3–58%) (American Psychological Association, 1994). Therefore, the following studies must be interpreted with caution. Specific diagnostic criteria for PTSD were not widely available until 1980. The term "psychic trauma" which included extreme fear reactions, grief, agitation, and depression was more often found in the literature. Also, few, if any, reliable screening instruments for childhood PTSD had been developed which severely undermined reliable estimation of the prevalence of PTSD (Galante & Foa; 1986; Yule & Williams, 1990).

In one of the earliest studies of at-risk children, Terr (1979) noted that the incidence of psychic trauma was 100% among 26 children involved in the Chowchilla bus-kidnaping. This rate was independent of the child's background and developmental history (Terr, 1979). Interestingly, in a separate study, the prevalence of "extreme fright" and psychic trauma was 40% in an age, race, and sex-matched "normal" control group chosen from the same school district as the kidnap victims (Terr, 1983), an unexpectedly high rate among so-called "normal" school-aged children.

Two additional studies provide estimates for PTSD among children exposed to civilian acts of violence. Pynoos et al. (1987) examined the occurrence of PTSD in 159 children one month after an attack by a sniper on their school playground. Seventy-seven percent of the children under direct threat (i.e., those on the playground) had moderate or severe PTSD as measured by the PTSD Reaction Index. Moderate or severe PTSD was also high (67%) among children not exposed to the sniper but at the school on the same day (Pynoos et al.).

More recently, Schwarz and Kowalski (1991) assessed 64 preadolescent school children six months after a shooting spree by a woman in their school. Prevalence rates were presented separately for the three diagnostic categorizations of PTSD under *DSM-III*, *DSM-III-R*, and *DSM-IV*, and the PTSD Reaction Index. Using "conservative" symptom thresholds (i.e., symptoms occurring "much" or "most of the time"), the prevalence of PTSD under *DSM-III* was 16%. By contrast, the prevalence of PTSD under *DSM-III-R* was only 8%, and 9% under *DSM-IV* (Schwarz & Kowalski, 1991). Using "liberal" symptom threshold levels (i.e., symptoms occurring at least "a little of the time"), prevalence rates ranged from 91% under *DSM-III* to 50% for *DSM-III-R*, and 26% for *DSM-IV*. This study underlines the difficulty with comparing PTSD prevalence rates across studies which use different versions of the *DSM*. Arguably, it also points out the risk of not identifying true cases of PTSD when using the subsequent revisions of the criteria under *DSM-III-R* and *DSM-IV*.

Several investigations have examined the prevalence of PTSD among children exposed to war. Kinzie et al. (1986) conducted one of the first investigations using operationally defined diagnostic criteria to study the effects of war on 40 Cambodian refugees living in Oregon. Nearly four years after leaving refugee camps in Cambodia as adolescents, 50% met current *DSM-III* criteria for PTSD based on structured clinical interviews. More severe psychiatric effects were found in those who had been separated from family members (Kinzie et al., 1986). Sack et al. (1994) reported much lower rates (lifetime = 21.5%; current = 18.0%) in 200 Cambodian refugees in the United States. Similarly, in a study of 840 war-affected children from Lebanon, Saigh (1991) observed a much lower rate of current PTSD (32.5%). Interestingly, levels of PTSD were consistent across routes of exposure (direct, observation, and indirect) (Saigh, 1991).

Several studies have investigated the prevalence of traumatic reactions in children following natural and manmade disasters. Handford et al. (1986) found higher than normal anxiety scores on children and adolescents from 35 households 1.5 years after the "Three Mile Island" nuclear disaster. None of the children, however, met criteria for a diagnosis of PTSD based on structured interviews. Similarly, Earls et al. (1988), using structured diagnostic interviews, found no cases of PTSD in 32 children and adolescents one year after a flash flood, although many met several criteria for the disorder.

By contrast, McFarlane, Policansky, and Irwin (1987) found a high frequency of PTSD symptom clusters (94%) obtained from parent and teacher versions of the Rutter Scales in 808 children two months after large-scale brushfires in Australia. Similarly, Milgram, Toubiana, Klingman, Raviv, and Goldstein (1988) observed a 40% prevalence rate for PTSD in children one month after a bus accident. Bradburn (1991) reported prevalence rates of 27% for moderate PTSD and 36% for mild PTSD in 22 children aged 10–12 years, some 6–8 months after the San Francisco earthquake. Of 179 children aged 2–15 years who were examined two years after the Buffalo Creek disaster, 37% received probable PTSD diagnoses based on retrospective examination of records (Greene et al., 1991).

A number of large-scale investigations of PTSD in children were conducted following Hurricane Hugo which struck South Carolina in 1989. Based on self-report data, Lonigan et al. (1991) reported PTSD prevalence rates of 5.06% in a no-exposure group, 10.35% in a mild, 15.54% in a moderate, and 28.95% in a high-exposure group of hurricane survivors. The overall prevalence rate for PTSD in the sample was 5% ($n = 5687$) nearly three months after the hurricane (Shannon, Lonigan, Finch, & Taylor, 1994). Similarly, Garrison, Weinrich, Hardin, Weinrich, and Wang (1993) reported current prevalence rates ranging from 1.5 to 6.2% one year after the hurricane in 11–17 year-olds.

From the above studies it can be seen that reliable estimation of the prevalence of PTSD in children and adolescents is extremely difficult, particularly from data collected before the operationalizing of PTSD in *DSM*. Moreover, there is considerable variability in prevalence estimates depending upon the age of the child, time since the trauma, assessment methods used, and under which version of *DSM* caseness was established.

5.16.2.2.2 Etiology

In contrast to most of the phenomenological classifications in *DSM-IV* (American Psychiatric Association, 1994) and *ICD-10* (World Health Organization, 1992), PTSD is one of the few psychiatric disorders which specifies an etiological agent. However, *DSM-IV* also recognizes that, at worst, only slightly more than half (58%) of those exposed to a trauma go on to develop PTSD (American Psychiatric Association, 1994). Thus, while trauma may be a necessary agent in the development of PTSD, it is clearly not a sufficient one (Yehuda & McFarlane, 1995). It is with this background that etiological theories have emerged to explain the development of PTSD since the early 1980s. A complete review of the etiological theories of PTSD is beyond the scope of this chapter and the interested reader should consult Foa et al. (1989) and Friedman, Charney, and Deutch (1995) for details. This chapter focuses on three models which have received considerable attention from researchers and for which there is limited empirical support or ongoing investigation. However, it should be noted that none of the etiological models put forward to date can explain adequately the full range of symptoms seen in PTSD (Yehuda & McFarlane, 1995).

5.16.2.2.3 A learning theory account of PTSD

Numerous researchers have proposed the use of Mowrer's (1960) two-factor learning theory to explain the development of PTSD (see Foa et al., 1989 for a review). Mowrer's is a conditioning model, incorporating elements of both Pavlovian and operant conditioning. As applied to PTSD, the traumatic event is an unconditioned stimulus that elicits certain involuntary responses: (i) orientation to the threat cue; (ii) autonomic arousal; (iii) fear; and (iv) the behavioral "flight or fight' response (Southwick, Bremner, Krystal, & Charney, 1994). Because of their proximity to the threatening event (the unconditioned stimulus (UCS)), previously neutral stimuli become conditioned stimuli (CS), capable of eliciting the same involuntary responses (conditioned response (CR)) as the trauma itself. For example, a child struck while crossing the street by a yellow taxicab (UCS) becomes overwhelmed with fear and intrusive thoughts of the accident (CR) upon any subsequent exposure to yellow taxicabs (CS).

Under normal conditions, repeated exposure to yellow cabs (CS) without being involved in an accident (UCS) should lead to extinction of the conditioned anxiety response (CR). However, with PTSD (Keane, Zimmering, & Caddell, 1985), this extinction fails to occur because the traumatized individual is negatively reinforced (i.e., their anxiety goes down) for avoiding the CS (e.g., yellow cabs). In addition, other previously neutral stimuli associated with the CS, such as the color yellow itself, may also elicit the conditioned anxiety response through the process of stimulus generalization. Finally, the CS themselves may go on to condition other nontrauma-related stimuli (higher order conditioning). Thus, traumatized persons may find themselves confronted with a wide array of anxiety-eliciting cues in their environment that cause persistent hyperarousal, intrusive recall of the traumatic event, and behavioral avoidance of the conditioned cues (Keane et al., 1985).

5.16.2.2.4 An emotional processing model

Observations from work on experimentally conditioned neuroses have led to the development of an emotional processing account of

PTSD derived from Lang's (1985) information processing theory of anxiety which, in contrast to conditioning models, takes into account subjective appraisals of the traumatic event in the development of PTSD. According to the emotional processing model (Foa & Kozak, 1986), traumatic events lead to the development of fear structures in memory that act to prevent further traumatization. These fear structures contain information about the objective characteristics of the trauma, the individual's responses to the trauma, and their subjective appraisal of the dangerousness and meaningfulness of the event (Foa & Kozak, 1986). Activation of this fear structure leads to increases in arousal, reexperiencing, and avoidant behaviors.

The meaning the individual attaches to the trauma, and their responses to it, are as important as the objective characteristics of the trauma. Specifically, the emotional processing model postulates that traumatic events can lead to changes in one's fundamental assumptions about safety and self-efficacy. This in turn leads to the development of new assumptions which attach increased threat value to a variety of previously neutral or even safety-signaling cues (Foa & Kozak, 1986). Consequently, many stimuli in the environment can now activate the fear structure, making it more readily accessible in memory than other potentially adaptive emotion networks, and diverting attentional resources from other nontrauma-related cues.

Ultimately, the fear structure can only be consolidated into long-term memory when corrective information (both cognitive and affective) is incorporated to develop a new information structure (Foa & Kozak, 1986). Foa et al. (1989) suggest that *in vivo* and imaginal exposure provide the type of corrective feedback necessary for consolidation of the fear structure. Specifically, increased contact with feared stimuli leads to habituation of the anxiety response, which they argue is a form of corrective feedback, as well as changes in the individual's beliefs about the likelihood of being retraumatized in the presence of neutral cues and safety signals.

5.16.2.2.5 A neurobiological model of PTSD

Numerous interrelated brain systems are activated during stressful events and have been implicated in the development of PTSD (see Friedman et al., 1995 for a review). The relationships among these systems are complex and poorly understood (Southwick et al., 1994). Given the complex interrelationships among brain systems, it is extremely unlikely that any one-to-one correspondence exists between PTSD symptoms and particular neurotransmitters or hormones (Southwick et al., 1994). Still, three systems have received considerable attention: the noradrenergic system, the hypothalamic pituitary (HPA) axis, and the endogenous opiates. These systems assist our understanding of the phenomenology of PTSD and have important implications for pharmacological treatment of the disorder (Sutherland & Davidson, 1994).

First, it has been suggested that these persistent symptoms of arousal reflect sympathetic nervous system dysregulation resulting from changes in the noradrenergic system (Southwick et al., 1994). During stressful events, central and peripheral levels of the neurotransmitter norepinephrine (NE) are increased leading to increases in heart rate and blood pressure and the experience of fear. These increases appear to serve an adaptive function as they arouse the individual and activate centers of the brain important to orienting to external stimuli, selective attention, and memory encoding of the event. However, repeated or uncontrollable stress may lead to chronic elevations in NE and alterations in NE receptors in the locus coereleus, resulting in the persistent physiological arousal seen in PTSD. There is an emerging body of evidence suggesting that veterans with PTSD have increased levels of NE and changes in noradrenergic receptivity compared with veterans without PTSD and veterans with other disorders (see Southwick et al., 1994 for a review). In addition to its effects on arousal, Pitman (1989) has suggested high states of NE-mediated arousal may "supercondition" traumatic events in memory, leading to persistent re-experiencing symptoms.

Second, there is increasing evidence that chronic or uncontrollable stress produces changes in activity of the corticotropin-releasing factor (CRF) and the hypothalamic–pituitary–adrenal (HPA) axis. The HPA system is known to play an important role in the stress response: releasing cortisol and adrenocorticotropic hormone (ACTH) assists in energy metabolism and tissue repair. Glucocorticoids exert negative feedback on the HPA axis to help maintain these hormones at nontoxic levels. Additionally, it appears that the NE and HPA systems stimulate each other, primarily through the action of CRF, leading to a mutually reinforcing feedback loop (Southwick et al., 1994).

Again, there is evidence that exposure to repeated or uncontrollable stress appears to cause the HPA system to become highly sensitized, leading to greater fluctuation in cortisol levels over a 24 h period (Southwick et al., 1994). A number of studies with combat veterans (see Southwick et al., 1994 and Yehuda & McFarlane, 1995 for a review) have found decreased levels of urinary cortisol in those with PTSD compared with psychiatric and normal controls, as well as changes in the number and receptivity of glucocorticoid receptors in the brain. Interestingly, Southwick et al. (1994) note that in animal studies, chronic elevation of glucocorticoids has been associated with damage to the hippocampal region and learning deficits, which may help explain the short-term memory impairments found in patients with PTSD.

Third, endogenous opiates are also released during periods of acute stress, leading to increased pain thresholds which may allow the individual to survive life-threatening events (Southwick et al., 1994). Again, however, it has been hypothesized that exposure to chronic and uncontrollable stress leads to increased sensitization of the opioid system such that lower levels of stress continue to produce the analgesic response (Maier, 1986). This response has been shown in Vietnam veterans during exposure to trauma-related cues (van der Kolk, Greenberg, Orr, & Pittman, 1989) and may contribute to development of avoidance and numbing symptoms (Southwick et al., 1994). Moreover, it has been suggested that the heightened sensitivity of the opioid system may play a role in intrusive recall of the trauma through its effects on NE and the consolidation of memory (McGaugh, 1990).

While other areas of the central nervous system are certainly involved in the pathogenesis of PTSD, the above findings are pertinent. First, dysregulation of the HPA and noradrenergic systems may explain why individuals with PTSD frequently suffer from chronic levels of hyperarousal, hyper-reactivity to trauma-related stimuli, emotional numbing, and difficulties with concentration and memory (including intrusive imagery) (Southwick et al., 1994). Second, these findings further our understanding of why not all individuals develop PTSD. Rather than viewing PTSD as a normal reaction to an abnormal event, it may be a complex psychological and biological response to trauma involving the phenotypic expression of vulnerabilities to the disorder (Yehuda & McFarlane, 1995). Finally, the ability to distinguish individuals with and without PTSD based on the role of HPA and noradrenergic dysregulation provides further evidence of the validity of the disorder, and has significant implications for the assessment and treatment of PTSD in both adults and children.

5.16.2.2.6 Characteristics of the trauma and other risk factors for PTSD

Regarding the trauma itself, revisions to Criterion A under *DSM-IV* aim to provide a tighter objective definition of the event, and recent research with children has concerned the relationship between the objective characteristics of the stressor and subsequent symptoms. A number of studies have reported the presence of a dose–response relationship among children involved in a sniper attack on a school (Pynoos et al., 1987), a shipping accident (Yule et al., 1990), an earthquake (Pynoos et al., 1993), a hurricane (Lonigan et al., 1991), and during war (Kuterovac, Dyregrov, & Stuvland, 1994). Similarly, attention to refining the descriptions of the nature of children's traumatic experiences has led to a more precise identification of the specific features of traumatic events which are associated with risk of PTSD. For example, exposure to direct life threat, witnessing mutilating injury or grotesque death (especially of family members or friends), and hearing unanswered screams for help were associated with more severe pathology among children and adolescents after a shipping disaster (Yule & Williams, 1990) and an earthquake (Pynoos et al., 1993).

The relationship between trauma and response has been described in detail by Terr (1991) who distinguishes between Type I and Type II traumatic events. Type I traumas are single, sudden, severe, acute stressors (e.g., natural disasters). By contrast, Type II traumas, such as childhood sexual or physical assault, are typically repeated, chronic, and expected. Terr (1991) suggests that Type I traumas are more likely to result in classic PTSD symptoms, whereas children exposed to Type II traumas are more likely to show characterological problems. While this distinction is of potential clinical relevance, it has yet to be empirically investigated and should not be overly applied. Indeed, traumatic events experienced during war are often repeated and chronic, but the associated psychopathology contains a high prevalence of classic PTSD symptoms (Kuterovac et al., 1994).

It is recognized, however, that stressors cannot be completely defined in objective terms (Rachman, 1980), and there is increasing interest in cognitive threat appraisal and attributional processes among children and adolescents (Joseph, Brewin, Yule, & Williams, 1991, 1993). The revised diagnostic criteria for the defining stressor in *DSM-IV* now include immediate responses of intense fear, helplessness, or horror (or disorganized or agitated behavior in children) in the face of actual or threatened life threat or injury to self or others (American Psychiatric Association, 1994). This stands in important contrast to previous formulations in which the stressor was seen as one that would cause significant distress to almost anyone.

There is evidence that attributional processes can mediate symptoms in child survivors. In young survivors of a shipping accident, Joseph, Brewin, Yule, and Williams (1993) found that more internal and controllable attributions were associated with intrusive thoughts and depressive feelings one year after the accident. Yule et al. (1990) have presented some evidence of a subjective dose–response relationship in survivors of the same accident. Children who had wanted to go on the cruise but had not obtained places were far less badly affected than those who went on the trip, but more badly affected than those who had never wanted to go.

Whatever the nature of the traumatic event and the child's appraisal of it, there are clearly a number of risk and protective factors which influence the development of disorder in children. Girls have been found to be more vulnerable than boys in a number of studies including a shipping disaster (Yule, 1992), a hurricane (Lonigan et al., 1991), and an earthquake (Pynoos et al., 1993) across a variety of self-report measures. Interestingly, Burke et al. (1986) found boys' distress to be higher than girls' five months after a flood, but reported that 10 months after the flood, girls showed more distress.

Age has been thought to be a factor in the development of PTSD. However, following the earthquake in Armenia, age was not found to correlate with Stress Reaction Index scores (Pynoos et al., 1993). Keppel-Benson and Ollendick (1993) argued that younger children may be protected from strong emotional reactions because of their limited cognitive capacity, particularly their awareness of threats of harm. Preliminary evidence of this hypothesis was found by Green et al. (1991) who noted that preschoolers' perceptions of threat were unrelated to symptomatology following the Buffalo Creek disaster. However, there are insufficient studies to determine whether children of different ages are at different risk of developing PTSD.

Studies of premorbid risk factors in children are also very limited. As yet, no studies have investigated systematically pretrauma abuse histories, psychological functioning, or familial psychiatric history in relation to the child's subsequent risk of PTSD. However, regarding premorbid ability and academic attainment, Yule and Udwin (1991) found that among survivors of the Jupiter shipping accident, an increased risk of PTSD was associated with low pretrauma attainment at school.

In addition to pretrauma risk factors, events and processes following exposure have been shown to influence development of the disorder. Family reactions to a disaster may be important moderating factors in the development of childhood PTSD. Studying families after the Australian bushfires, McFarlane (1987) found that parents' adjustment was an important determinant of the adjustment of their children: families who found it difficult to share their immediate reactions had more trouble with long-term adjustment. Equally important, the child's reaction to the fires affected the family's adjustment, demonstrating the reciprocal interactions among family members.

Pynoos (1994) argues that there are many interacting critical factors which play a role in the progression from traumatic exposure to subsequent psychopathology. These include social structures, community organization, family functioning, and the individual stressful challenges to the child. Pynoos' (1994) developmental model provides a useful framework for understanding this pathway, and implicates potential areas for prevention and treatment.

5.16.2.2.7 Developmental course

Being explicitly developmental, Pynoos' (1994) model (see above) provides a useful framework for understanding the course of post-trauma reactions in children. Nevertheless, there are very few systematic studies which have examined the long-term effects of exposure to traumatic events on children.

Two months after the Australian bushfires, children who had been exposed were rated as less disturbed on Rutter's screening scales than a nonexposed comparison group studied elsewhere (McFarlane et al., 1987). However, by eight months, both parents and teachers reported significant increases in the numbers of children at high risk of psychiatric disorder, and these high rates were maintained at 26 months. Around a third of this sample was still preoccupied with the event more than two years later (McFarlane et al., 1987).

Fourteen months after a school sniper attack in Los Angeles, Nader, Pynoos, Fairbanks, and Frederick (1991) found that the majority of children felt afraid when they thought about the attack, and most were specifically afraid of recurrence. In her follow-up of child survivors of a bus hijacking, Terr (1979, 1983) found very few children who were fear free some five years after the event. Thus it appears that fear may be a long-lasting consequence of traumatic events in children.

Assessing Cambodian refugees who had emigrated to America four years earlier as adolescents, Kinzie et al. (1986) found a range of intrusive and avoidance phenomena (50% of the sample suffered from PTSD), but also major depressive disorder. Prolonged depressive symptoms were found in this sample of adolescents and young adults who had been exposed to massive and repeated trauma.

Results from a six to seven-year follow-up of survivors of the Jupiter shipping accident (Yule & Udwin, 1991; Boyle et al., 1995) revealed soberingly high rates of psychiatric disorder. Preliminary results from a cohort of 98 survivors showed that of the 51% who met criteria for PTSD at some time since the disaster, 60% had PTSD which lasted for up to two years, with a further 18% having PTSD for five years. Rates of other disorder, including panic, separation anxiety, OCD, substance abuse, dysthymia, and hypomania, were also elevated compared with a control group. Thus, a range of symptoms may persist over several years. Children do improve over time, however. After a school bus crash, high levels of acute stress reactions during the first week dropped markedly over the following nine months, although initial levels of distress predicted later ones (Milgram et al., 1988).

Evidence from the Jupiter follow up (Boyle et al., 1995) and other studies suggest that the severity of the stressor may be one of the most important factors in determining the severity of later pathology. However, while Kinzie et al. (1986) found no direct relationship between extent and type of exposure and psychiatric diagnosis four years later among Cambodian refugees, their current living situation showed a strong relationship to diagnosis. McFarlane's (1987) data show family factors to be an important variable moderating outcome. It seems that the course of post-traumatic stress symptoms such as intrusive re-experiencing and avoidance of feelings follow a different time course than symptoms of depression and anxiety, both of which increase after the first six months postdisaster. Clearly, there will be a complex interaction over time of factors which influence the course and chronicity of stress reactions (Pynoos, 1994) and further research is needed to delineate these factors.

5.16.3 CONCEPTUALIZATION AND CLINICAL FORMULATION

5.16.3.1 Multimodal Assessment

As stated above, PTSD is a cluster of symptoms overlapping several domains of functioning. As such, the interview should be geared towards assessing all aspects of client functioning. This can be accomplished through a direct interview with the child as well as the family and teachers, self-report inventories and diaries, and psychophysiological recording. In addition, the therapist should try to gather all available information possible about the exact nature of the trauma from other witnesses, news reports, and police/rescue personnel. Finally, establishing the nature and extent of impairment through review of available medical and school reports is important. Experience has shown that these additional sources of information are important to help the interviewer understand the sequence of events during the trauma and often reveal symptoms that either are not readily admitted or remembered by the child and his or her family.

5.16.3.1.1 Interviewing the child

Pynoos and Eth (1986) have developed a technique for interviewing young children shortly after the witness of a traumatic or violent event, although it has broad applicability to all types of direct and indirect trauma experienced by children. The interview is broken down into three components: opening, trauma, and closure. "Opening" refers to the establishment of a focused but free discussion of the traumatic event. This is accomplished by: (i) communicating to the child that the interviewer has experience with talking to children about their traumatic experiences; (ii) giving the child pencil and paper and asking them to "draw whatever you would like but something you can tell a story about"; and (iii) encouraging the child to elaborate further (verbally or through drawing) on the story.

During the second stage of the interview, aspects of the child's drawing are linked explicitly to some aspect of the traumatic event by the therapist to facilitate emotional release. For example, the therapist might say, "I bet you wish that your father could have been saved in the end like the clown." Once the therapist has judged that the child is ready to proceed emotionally, he or she may say, "Now is a good time to tell what happened and what you saw." The child is supported in their focus on the traumatic event by asking them to draw the traumatic event, focusing and describing the sensory aspects of the event, the worst moment, any violence or mutilation, and how they coped with these experiences. Pynoos and Eth (1986) have also suggested that the child be encouraged to describe any plans or thoughts they had or have about ways in which they could have remedied the situation, feelings of blame, the desire for retaliation and fears of counter-retaliation, and feelings of control. Then the therapist inquires about previous traumas, recent dreams that may be remembered, their concerns about the future, and current stresses.

In the third and final stage of the interview, the process of termination is begun. This is accomplished by having the child review and summarize the session, normalizing the child's reactions to the traumatic event, and linking the trauma to the original drawing or story (Pynoos & Eth, 1986). In addition, the therapist may discuss with the child information they have about the expected course of the disorder. This is done by helping them identify potentially fear-eliciting, trauma-related stimuli and their potential reactions to these stimuli outside the session. To bolster the child's self-esteem, the therapist may remark on the child's courage during the event and in retelling the story during the interview. Finally, the child is asked to describe what was helpful or disturbing about the interview process and the therapist expresses his or her respect for the child's views and the privilege of having shared the interview experience with them. While the above interview technique does not specifically include any standardized assessment of PTSD symptomatology, it has proven useful in raising awareness of the sensitive nature of the trauma interview and the importance of therapist skill in obtaining accurate information.

5.16.3.1.2 Childhood measures of post-traumatic distress

Since the mid-1980s, a variety of interview techniques and instruments have been developed to assess PTSD in children directly. The majority have been adapted from semi-structured psychiatric interviews or self-report questionnaires originally developed with adults. In addition, several pre-existing measures, originally designed to assess childhood anxiety, fear, depression, and behavioral disturbance have been applied to the study of childhood PTSD. This section will introduce the reader to some of the more widely used instruments. Readers interested in a more comprehensive review of the available measures of childhood PTSD and their psychometric properties are referred to Nader (1996) and McNally (1991).

Perhaps the most widely used measure of PTSD symptomatology is the IES (Horowitz et al., 1979). It assesses the cardinal symptoms of PTSD (intrusion and avoidance), and has been used with children aged eight years and over (Yule & Udwin, 1991; Yule & Williams, 1990). It has proven particularly useful in the assessment of post-traumatic stress when used in conjunction with measures of childhood anxiety, fear, and depression (Stallard & Law, 1993; Yule & Udwin, 1991). Such measures include the Birleson Depression Inventory (Birleson, 1981), the Children's Manifest Anxiety Scale (Reynolds & Richmond, 1978), and the Fear Survey Schedule for Children (Ollendick, 1983). However, it should be noted that factor analyses suggest that some items of the IES are misunderstood by children and should be replaced (Yule et al., 1990).

Another widely used measure of childhood PTSD is the Children's Post Traumatic Stress Reaction Index (CPTS-R) (Frederick, 1985b). In a number of major studies of child trauma (Nader et al., 1991; Pynoos et al., 1987, 1993; Pynoos & Nader, 1988), the CPTS-R has been shown to have good internal consistency and to relate well to clinical judgement of PTSD severity (Yule & Udwin, 1991). Saigh's (1989) Children's Posttraumatic Stress Disorder Inventory is a structured inventory designed to explore *DSM-III* PTSD symptoms and has good psychometric properties. Finally, the Children's Impact of Traumatic Events Scale-Revised (CITES-R) (Wolfe, Gentile, Sas, & Wolfe, 1991) was developed to assess the impact of sexual abuse on children.

There are a number of semistructured interviews based directly on *DSM* criteria available that allow the interviewer to diagnose PTSD in the child. These include: the Clinician Administered PTSD Scale for Children (CAPS-C; Nader, Kriegler, Keane, Blake, & Pynoos, 1994); the Diagnostic Interview Schedule for Children (DISC; Shaffer et al., 1996); and the Diagnostic Interview for Children and Adolescents Revised (DICA; Reich, Shakya, & Taibelson, 1991). All require the interviewer to be trained in the administration of the scale, and have been shown to possess adequate validity and reliability (cf., Nader, 1995).

Unfortunately there has been a dearth of standardized approaches to the assessment of stress reactions in children less than eight years of age. While children between three and eight years can often give adequate verbal responses to questions from standardized measures used with older children, there is a need to develop measures particularly suited for young children. This is particularly important in light of the legal implication of PTSD interviews and emerging data on suggestibility in children.

Still, it has been argued that the rush to develop semi-structured interviews to elicit and quantify PTSD in children is somewhat misguided in that they simply rephrase *DSM* criteria into questionnaire format (Yule, 1994). As discussed above, many of the *DSM* criteria are irrelevant to children, and thus semi-structured interviews may have only limited validity in assessing the complete range of traumatic reactions observed in traumatized children. Moreover, it should be recognized that the interview is itself both a potentially threatening and therapeutic experience, requiring considerable skill and sensitivity on the part of the interviewer, and a firm understanding of child development. The establishment of rapport and a safe environment in which the child can discuss painful and angry feelings are very important to acquiring accurate information. The use of semistructured interviews and self-report questionnaires must always be placed within this context.

Finally, physiological measures such as galvanic skin response, heart rate, and respiration may prove useful in the assessment of PTSD, although they have received limited attention in the childhood PTSD literature (Finch & Daugherty, 1993).

5.16.3.1.3 Interviewing the parent

While the importance of interviewing children directly has been clearly established (Nader & Pynoos, 1989; Reich & Earls, 1987; Terr, 1979), children may not report the full range of PTSD symptoms (Nader & Fairbanks, 1994). Thus, a comprehensive psychiatric assessment should include a direct interview with the parents or primary caregivers. Most of the semistructured diagnostic interviews available include both child and parent versions which allow the interviewer to cover all symptoms systematically with parents and child. This is particularly important where the symptom may be of a particularly embarrassing nature, as with enuresis, thumb-sucking, and crying, or where the child may be unaware of their behavior, as in "clinging" or sleep disturbances.

Beyond a comprehensive coverage of the child's developmental history and current symptom state, it is important to establish the time-line of events leading up to, including, and following the trauma as this may help the therapist in assessing the child's accuracy of recall (Nader, 1995). Young children (less than eight years of age) are prone to time distortions because of age-appropriate levels of cognitive maturation. However, even older children may confuse the sequence of events because of extreme emotional arousal and chaos experienced during the traumatic event.

5.16.3.1.4 Discrepancies in parent and child reports

Children often minimize the extent and severity of their own disruptive behaviors, whereas parents often overemphasize these symptoms while remaining unaware of particular fears or negative emotions (Nader & Pynoos, 1989). An additional problem with parental reports is that parents may be inclined to minimize the effect of a trauma on their child and thus under-report symptoms (Sternberg et al., 1993). This may occur as a function of the parents' own abhorrence to the trauma and its recall. It is important then that the therapist be attentive to the parents' emotional state and level of arousal when recalling the trauma.

5.16.3.2 Treatment Formulation

From the above outline of multimodal assessment, it follows that treatment formulation will draw on a number of sources. Conventionally, treatment planning will be based on an assessment of current difficulties, the child's (and his or her family's) premorbid functioning, and currently available resources. Additionally, in trauma work, the kind of intervention offered will depend on how recently the traumatic event occurred.

Where children are seen within days or weeks after the traumatic event, the aim of intervention is to facilitate recovery rather than to treat symptoms. In general, recovery will be facilitated by retelling the facts of the incident, expressing feelings associated with it, normalizing reactions, educating and informing about the expected course, and by the enhancement of coping strategies (see Section 5.16.4.1.2 and Pynoos & Eth 1986). Nevertheless, effective intervention at this stage will depend also on a thorough assessment of the child's living situation and available resources. Work with carers is necessary to assist them to help their children, especially when they have themselves been directly involved in the incident. Practical issues of social welfare may arise, for instance, in cases where there is ongoing community violence, or where the child has suffered a parental bereavement. Here, multidisciplinary work is required so that as secure and safe an environment as possible is available to the child in the immediate aftermath and short term following the incident.

Treatment formulation will differ when children are referred months to years after the event. A comprehensive pretrauma history from the child's carers will help in understanding the child's usual reactions to stress and their ways of coping: whether current symptomatology is in part a function of prior temperament; what changes in behavior the traumatic event precipitated; and in setting appropriate treatment goals. Considering the child's developmental level will allow one to assess which if any of the presenting complaints are normal age-appropriate behaviors (e.g., separation anxiety), as well as guiding the choice of treatment strategies. Given the important mediating role of parental reactions and fears (McFarlane, 1987), assessment of all family members is usually necessary, both to determine whether adults or siblings also require intervention, and to advise carers on management of their children. Since the severity of the trauma is an important factor in determining the severity of later pathology (Yule, 1994), assessing the extent and type of exposure is necessary, and to address multiple episodes within a single traumatic event (Pynoos & Nader, 1993).

Treatment goals will differ according to the pattern of presenting problems, but common goals normally will include helping the child to understand the nature and effects of trauma, facilitating his or her ability to think and talk about the event without debilitating anxiety, and reducing the intensity and frequency of intrusive, avoidant, and hyperarousal symptoms (Ribbe et al., 1995). Prioritizing goals will be done collaboratively with the child and their carers, and will address those symptoms that are impacting most severely on the child's day-to-day functioning.

Common to most treatment approaches is the notion that the traumatic event requires adequate emotional processing (Rachman, 1980), and at the core of most psychosocial treatment methods is imaginal exposure to the event to facilitate such processing (see below). Also, given the range of reactions to critical incidents, a flexible approach to treatment is called for by which the child's coping strategies to deal with distressing symptoms are developed and enhanced. To take a common example of symptom management, sleep hygiene techniques can often be therapeutically beneficial while addressing the central trauma. While clinicians must be alerted to their own avoidance of the most difficult aspects of the child's experience, prioritizing areas of particular difficulty with the child and then bolstering coping strategies may increase a sense of mastery and self-efficacy while reducing feelings of helplessness and victimization.

Children with PTSD may present with other Axis I comorbidity and chronic pain reactions resulting from injury, and in this case, treatment formulation will be modified accordingly. In traumatic bereavement, Dyregrov (1991) recommends that the traumatic nature of the death needs to be addressed before grieving can proceed.

Given the cascade of events that may follow a traumatic incident, treatment formulation will also address secondary adversities, with the aim of preventing further complications. Often, these may be traumatic reminders, ongoing legal processes, and anniversaries. It is common, for example, that academic attainment drops following exposure (e.g., Yule, 1994), and this in turn may potentially impact on the child's functioning in other areas and later into adulthood. Therefore, a comprehensive treatment plan may include "pulsed intervention" at times of expected stress such as changing schools and anniversaries (e.g., James, 1989).

5.16.4 TREATMENT

While there is a growing number of single case studies and detailed clinical descriptions of treating traumatized children, there are as yet no randomized controlled outcome trials. In the main, however, treatment approaches are broadly cognitive behavioral: the guiding principle is that exposure to trauma-related cues and memories in tolerable doses is needed to reduce PTSD symptoms. Professionals can help by creating a relatively safe environment in which such recounting can take place. Given the nature of many traumatic events, early intervention is often best done in groups and through existing structures such as schools. Work has also focused on contingency planning and disaster management using a public health approach which involves community resources. There is little available evidence for the effectiveness of pharmacological treatment of PTSD in children.

5.16.4.1 Psychosocial Approaches

5.16.4.1.1 Preventative measures and contingency planning

Traumatic events are by their nature unexpected and uncontrollable. Nevertheless, it is well recognized that much can be done to alleviate distress in children if the unexpected is planned for. Outside the family, school is a primary source of social support for children, and a number of authors (Klingman, 1993; Pynoos & Nader, 1988; Yule & Gold; 1993) have provided guidelines for how schools can plan to help child survivors of catastrophes. Particular emphasis is placed on schools and mental health professionals working together.

Planning for disasters will not prevent them from happening, but by anticipating many of the actions needed, schools may reduce the impact of critical incidents. Thus, Yule and Gold (1993) recommend a number of short-, medium-, and long-term tasks for school staff to be alerted to. School staff should be made aware of the likely psychological effects of disasters on children, parents, and teachers before disaster strikes through liaison with local child mental health services. In the event of a traumatic incident, immediate action should include ensuring that correct information can get into and out of the school, ensuring that several staff have access to next-of-kin lists, setting up strategies to deal with enquiries, informing parents about what has happened with care and sensitivity and reuniting parents and children, nominating a press officer to deal with the media, informing staff and pupils in an appropriate and careful way, attempting to stick to normal routines as much as possible, and planning for attendance at funerals.

School staff should be briefed about what has happened, and after contacting relevant outside agencies, debriefing meetings can be set up for directly involved staff and children. Procedures for monitoring both staff and children should be set up, and strategies for allowing young people who want to express their feelings about the situation should be activated.

In the medium term, it will be important for children who remain at home or in hospital to be contacted, and arrangements made either for their return to school or for alternative teaching. Affected staff and children may continue to need support, and this will be achieved more easily if ground rules for working with outside agencies have been set up beforehand. Close liaison with parents at this stage will be necessary.

In the longer term, introducing strategies to continue to monitor vulnerable pupils and staff is useful, to decide how to mark anniversaries, and to be aware that legal processes and media attention may bring back distressing memories and cause temporary upsets within the school. Schools should not have to deal with such enormously difficult issues such as death and bereavement for the first time following a crisis, and it is recommended that schools plan the curriculum to work with rites of passage as a matter of course.

Both Klingman (1993) and Yule and Gold (1993) advise that classroom interventions by teachers can be effective in defusing and normalizing emotions, not least by addressing rumors and myths about the disaster. Classroom interventions will include monitoring for high-risk children, since in themselves, they are no substitute for individual, group, or family interventions when needed (Pynoos & Nader, 1993).

5.16.4.1.2 Debriefing and crisis intervention

When schools are prepared for the unexpected, they are in an optimal position to provide early crisis intervention, with support from mental health professionals. Pynoos and Nader (1993) describe a number of "psychological first aid" strategies for common symptoms which can help to normalize the recovery process. They point out that these must be developmentally appropriate and provide a number of examples of techniques or strategies for use by teachers in schools.

A more widely used technique is Critical Incident Stress Debriefing (CISD) (Mitchell, 1983; Mitchell & Everly, 1993). Developed initially for use with emergency service personnel, debriefing has been adapted and used successfully with children following disasters (Dyregrov, 1991). Within a few days of an incident, the survivors are brought together in a group with an outside leader. During the introductory phase, the leader sets the ground rules for the meeting, emphasizing that they are there to share feelings and help each other and that what goes on in the meeting is private. The information should not be used to tease other children. No one has to talk, although all are encouraged to do so. The leader clarifies the facts of what actually happened in the incident. This allows for clarifications of any misunderstandings about how the traumatic event unfolded. They are asked about what they thought when they realized something was wrong, and this leads naturally to discussions of how they felt and their current emotional reactions. In this way, children share the various reactions they have experienced and usually learn that others have felt similarly. The leader labels their responses as normal (understandable) reactions to an abnormal situation.

Many children are relieved to learn that they are not the only ones experiencing strange feelings, that there is an explanation and that they are not going mad or crazy. The leader summarizes the information arising in the group, elicits and reinforces the existing coping strategies of the children, and educates them in what simple steps they can take to control some of their reactions. They are also told of other help available should their distress persist. The aim of debriefing is to facilitate the recovery process rather than to treat existing symptoms. The combination of normalizing reactions and teaching basic coping strategies can do much to enhance children's sense of mastery and control over their feelings. There is promising evidence from two studies which report reductions in distress among children following debriefing meetings.

Following the sinking in Athens of the cruise ship "Jupiter," which was carrying a party of British school children, Yule and Udwin (1991) described how they carried out a debriefing session with 24 survivors 10 days after the event. The debriefing meeting was carried out at school with the involvement of the survivors' teachers. As part of the meeting, the girls completed a screening battery consisting of the IES (Horowitz et al., 1979), the Birleson Depression Inventory (Birleson, 1981), and the revised Children's Manifest Anxiety Scale (Reynolds & Richmond, 1978). The girls were rescreened between 5 and 10 months later, and results were compared with the same self-report measures from a group of 15 girls from a different school who did not participate in any debriefing (Yule, 1992). The debriefing group showed significantly lower IES scores, and this effect was strongest for intrusive thoughts. The debriefing group also showed significantly reduced fears (Fear Survey Schedule) (Ollendick, Yule, & Ollier, 1991) compared with the control group. Scores on the depression and anxiety measures were slightly but not significantly lower. While these results are promising, some girls in the debriefing group went on to receive group treatment, making it impossible to isolate the effects of debriefing from subsequent therapy.

More convincing evidence is reported by Stallard and Law (1993), who carried out debriefing sessions with a group of seven young survivors of a minibus accident. The two debriefing meetings were carried out one week apart in school, and six months after the accident. The same screening battery as above was used before the first session, and children were subsequently rescreened three months later. Significant reductions were found in the group scores on all measures (PTSD, depression, and anxiety). Although no control data were obtained, given the stability of the scores in the six months before intervention, the authors argue that the improvement was related to the intervention.

Following a recent spate of well-publicized traumatic incidents involving school children, the call for debriefing and crisis counseling for all survivors is increasing. Although the available evidence is promising, there are no controlled studies demonstrating the efficacy of debriefing in reducing later distress. Given the debate about the usefulness of CISD among adults (Meichenbaum, 1994; Mitchell, 1996), there is a clear need for further evaluation of its efficacy with children. It is not known, for example, whether all survivors benefit, nor indeed when best to offer such debriefing.

5.16.4.1.3 Group treatment

Where critical incidents involve relatively large numbers of children, it makes sense to direct some therapeutic support through naturally existing groupings that are present in communities and schools. As with debriefing, the aims of such therapeutic groups will be to share experiences and feelings, to boost children's sense of mastery and control, and to share ways of solving common problems. Pynoos and Nader (1993) point out that providing a forum for the expression of feelings is not sufficient for groups: this may only renew feelings of anxiety unless a constructive, therapeutic approach is taken. A variety of approaches to group treatment have been described following earthquakes (Galante & Foa, 1986; Goenjian, 1993), a school sniper attack (Gillis, 1993), and shipping disasters (Yule & Udwin, 1991; Yule & Williams, 1990).

After a devastating earthquake in Italy in 1980, Galante and Foa (1986) carried out a group treatment program with 62 children from the most severely affected village. They describe a relatively structured approach, holding roughly monthly meetings throughout the academic year. Sessions lasted for an hour and each group consisted of four children from the same grade. Sessions focused on communicating about feelings (particularly about the earthquake), discussion and normalization of fear reactions, "active discharge of feelings about the earthquake," focusing on the future and rebuilding of their village, and sharing active coping strategies. Pre- and postgroup evaluation using the Rutter Children's Behaviour Questionnaire for Teachers (Rutter, 1967; Zimmerman-Tansella, Minghetti, Tacconi, & Tansella, 1978) showed a significant reduction in distress which compared favorably with children from other villages where children did not receive such support. Additionally, frequency counts were taken during sessions of repeating earthquake stories and the expression of related and unrelated fears. It is interesting that after an initial rise in these scores in the first few groups, they showed a dramatic decline only after a session where children looked to the future and were engaged in play to rebuild the village and provide safer housing.

A somewhat less structured approach was described by Yule and Williams (1990) with child and adult survivors of the Herald of Free Enterprise shipping disaster. Groups were open to any survivor to attend and met initially at monthly intervals over about a year, tailing off to every six to eight weeks thereafter. The children seemed to appreciate the opportunity to share their feelings with others without having to explain everything to outsiders. They took advantage of the cognitive behavioral problem solving approach by which efforts were made to help them identify things they were finding difficult and to use the resources of the group to develop solutions. The therapist working with the children also acted as a go-between with the parents' group. Yule and Williams (1990) suggested that an important part of group work with children following a disaster is that they have time together without the pressure of having to talk about the trauma.

Gillis (1993) worked with children following a school sniper attack. In small groups, both structured and more open-ended elements were used, including role play and re-enactment of the shooting. Gillis emphasizes that when groups are less structured, setting clear limits is important, for if behavior is out of control, it is likely to result in an increase in the children's anxiety. He found that running separate groups for boys and girls was better because of the different reactions they had to the attack, boys showing more externalizing reaction, and girls more internalizing ones. Groups comprised children of the same level of maturity, and Gillis suggests that it is optimal to work with groups of six to eight children.

It is notable that while the group treatment approaches reported above are well described and appear promising, there are no controlled studies providing evidence for the efficacy of such groups. There is a consensus that group interventions will be effective for some, but not all, children. However, one function of therapeutic groups is to screen for high-risk children who may need individual therapy. More generally, children whose problems persist despite group help should be treated individually.

5.16.4.1.4 Individual treatment

Broadly-based cognitive behavioral treatment methods aim to help survivors make sense of what has happened and to master feelings of anxiety and helplessness after a traumatic incident. Most survivors recognize that eventually they must "face up to the traumatic event." The problem for the clinician is how to help the survivor remember and re-experience the event and the emotions that it engenders so that the distress can be mastered rather than magnified. This will depend foremost on the establishment of a safe and trusting environment in which the traumatic event can be remembered and discussed. Therapists must be prepared to ask children about the most difficult aspects of the traumatic experience, but at the same time ensure that exposure to traumatic memories is paced so that the child does not experience overwhelming anxiety. For many children, talking directly about the traumatic event may be too difficult and other means of accessing traumatic memories must be found.

Asking children to draw their experiences often assists in the recall of both the event and the accompanying emotions. Pynoos and Eth (1986) provide a detailed account of how drawings may be used, not as projective techniques, but as a means of communicating about the experience (see Section 5.16.3.1.1). In younger children, play may be used similarly. Misch, Phillips, Evans, and Berekowitz (1993) gave children models and dolls representing the various components of the traumatic event which the children then used to answer questions about their experience.

At the core of cognitive-behavioral treatments with children is the use of imaginal and *in vivo* exposure techniques within a safe therapeutic environment. Results of controlled trials with adults generally support the use of exposure therapy for PTSD (e.g., Boudewyns & Hyer, 1990; Cooper & Clum, 1990; Keane, Fairbank, & Caddell, 1989), but trials of these techniques are still needed with children. Nevertheless, single case studies with children have shown very promising results.

Saigh (1987a) was the first to show that, as Rachman (1980) had predicted, longer exposure sessions than normal are needed if desensitization is to occur. He employed flooding techniques to treat a 14-year-old Lebanese boy who met criteria for PTSD after having been abducted and tortured. The imaginal flooding process consisted of 10 min of deep muscle relaxation, followed by 60 min of therapeutic stimulation during which the boy was instructed to imagine the particular details of four anxiety-evoking scenes. SUDS ratings were elicited at two min intervals during the aversive scene presentations. After seven flooding sessions, SUD levels decreased appreciably. Post-treatment and at four months follow-up, there were clinically significant treatment gains in self-reported anxiety (STAI; Spielberger, Gorsuch, & Luschene, 1970), depression (BDI; Beck, Rush, Shaw, & Emery, 1979), and misconduct, and virtually no arousal to the anxiety provoking scenes. The boy could complete all activities of a Behavioral Avoidance Test (BAT) involving a 10 min walk to the place where he had been kidnapped. The efficacy of such procedures was confirmed in a series of clinical replications involving multiple baselines across traumatic scenes (Saigh 1987b, 1989a, 1989b); and Saigh (1992) subsequently has summarized a five-stage intervention process involving education, imagery training, relaxation training, the presentation of anxiety provoking scenes, and debriefing.

Yule (1992) has described a different approach in the treatment of a 16-year-old boy who had survived a shipping accident two years earlier. The boy was asked to imagine and describe accurately what he had observed, heard, felt, smelled, and thought during the accident. The session was audiotaped and the boy went on to listen to the tape at home between sessions. Following treatment, significant clinical gains were observed on the standardized measures of anxiety and depression, and on the IES. After treatment, the boy could travel on a boat again for the first time in two years.

Therapeutic exposure under supportive circumstances seems to deal well with intrusion symptoms and behavioral avoidance. However, a flexible treatment approach which uses additional techniques to treat other common reactions such as sleep disturbance, separation anxiety, anger and conduct problems, prolonged grief reactions, generalized anxiety, and depression will be necessary.

Sleep disturbance is a common problem among children who have lived through traumatic experiences. A careful analysis will reveal whether the problem is one of getting off to sleep or in waking due to trauma-related nightmares. In the former case, implementing relaxation routines before bed and masking thoughts with music may help. In the latter, there are now positive cognitive behavioral techniques for alleviating nightmares, including dream restructuring approaches. In younger children, post-traumatic regressive behavior may include night time enuresis, and this may be treated using star charts and enuresis alarm techniques while addressing the central trauma.

Given the nature of traumatic events, children are frequently bereaved as a consequence. Pynoos and Nader (1988) emphasize the need to help children to distinguish their trauma-related responses from those related to grief, and suggest that where several children are bereaved, small groups can be beneficial in the initial stages. Dyregrov's (1993) account of the distinguishing features of traumatic bereavement implies that the traumatic nature of the death and post-trauma reactions need to be addressed before grieving can begin. Black (1993) uses a variety of techniques, including the use of drawings and play in her work with children who have been bereaved because of one parent killing another. Importantly, she also describes how family work—including that with new carers—is necessary in cases where a child has lost a parent.

Guilt, self-blame, helplessness, and vulnerability are common themes among older children and adolescents who have survived traumatic events. While these may be related to depressive features, they are often seen to have a different quality to them. Children may talk of omens, relating perhaps to a search for meaning as well as being related to issues of culpability. In work with younger children, it is important that any misunderstandings about the causes of the event are clarified, while with older children, cognitive restructuring may be used to counter misattributions of predictability, causality, and responsibility. Janoff-Bulman's (1985) work with adults about the shattering of key assumptions regarding self-invulnerability, life meaningfulness, and world justice are useful here.

Pynoos' (1994) developmental framework for understanding trauma reactions has a number of implications for therapeutic intervention. The model suggests that the interaction over time of many critical factors (including the complexity of the traumatic experience and the interactions of traumatic reminders, secondary stress, post-traumatic distress, and development) play a role in the progression from traumatic exposure to psychopathology. Each of these factors can be seen as a potential focus for intervention. Similarly, James (1989) describes the use of early intervention with subsequent "pulsed intervention" over time using multifaceted treatment approaches.

Finally, the most recent addition to the armamentarium of individual treatment techniques for PTSD is Eye Movement Desensitization and Reprocessing (EMDR) (Shapiro, 1989). The technique employs dual-attention tasks, most notably saccadic eye movements, to facilitate accelerated processing of traumatic memories and is fully described elsewhere (Shapiro, 1995). There is considerable controversy about the efficacy of the procedure in adults with PTSD, and no controlled trials with children. Some authors have described how EMDR can be adapted successfully and used with children (e.g., Greenwald, 1994). Cocco and Sharpe (1993) report the successful use of an auditory variant of EMDR with a 4-year-old boy diagnosed as suffering from PTSD following a violent robbery. Further research is clearly needed, but given the poor understanding of the rationale behind EMDR and the lack of any convincing evidence for its efficacy in work with children, the procedure should be used with care until outcome evaluation data and reliable protocols are available.

5.16.4.1.5 Community approaches

Following large-scale disasters, whole communities may be affected and this clearly requires a different kind of approach. The type of intervention will depend, broadly, on the nature of the disaster and the kind of community affected.

Early intervention is designed to help reduce levels of distress that may later lead to psychopathology and will allow for screening of vulnerable individuals. Often, the needs of the community will be for short-term therapeutic assistance rather than a traditional mental health service. Therefore, and because of the chaos that ensues following mass disaster, outreach services are recommended in the first place. Joyner and Swenson (1993) provide an account of Project Hugo, implemented after Hurricane Hugo struck South Carolina in 1989. Outreach teams of counselors quickly provided support and information to thousands of affected people. Telephone hotlines were set up, and fliers and information booklets produced. Joyner and Swenson stress the need for networking among emergency and support teams, as well as for building on the existing pastoral resources of the community (i.e., churches or schools).

Concentrating on the needs of children after the Australian bushfires, McFarlane (1991) has described how a preventative outreach program was implemented through schools using workbooks for pupils. The workbooks provided information about the bushfires as well as exercises designed to label and normalize common reactions, and to help children develop coping strategies with help from parents and teachers.

Where pre-existing community resources are either scarce or completely devastated by the disaster, the needs are different, and a modified approach is needed. Pynoos et al. (1993) characterized the psychological effects on children of the Armenian earthquakes of 1988 as severe, pervasive, and chronic. In this case, it was not possible to set up telephone hotlines or draft in teams of counselors from elsewhere: following an evaluation of existing services and a pilot screening of children, the emphasis here was on training local therapists to carry out brief psychotherapy and behavioral therapy (Goenjian, 1993). Therapists were selected carefully before training, and worked in pairs or teams such that they could support each other. Makeshift clinics were set up, and group and individual therapy, which included play, drawing, and storytelling, was implemented wherever possible including parents and teachers. Two therapeutic booklets, one for adults and one for children, were prepared and distributed. Importantly, considerable attention was paid to helping manage the stress of community leaders and the newly trained carers, themselves also affected by the devastation.

The trend in the twentieth century for war increasingly to affect civilians (particularly women and children) directly (UNICEF; 1996) has led to attempts by international relief agencies to meet the psychological needs of children in areas of recent and ongoing conflict (Kuterovac et al., 1994; Macksoud, Dyregrov, & Raundalen, 1993; Smith & Yule, 1995). The emphasis has been on rebuilding scarce local resources by training health workers, teachers, religious leaders, and others to deliver services at a variety of levels. Useful manuals that can be used by teachers and others in recognizing the signs of traumatic stress and providing initial treatment have been written after conflicts in Mozambique (Raundalen, Dyregrov, & Gronvold-Bugge, 1990; Richman, 1991, 1993), Lebanon (Macksoud et al., 1993), and Sri Lanka (Nikapota & Samarasinghe, 1993), but it should be noted that none of these has yet been evaluated in the field.

5.16.4.2 Pharmacological Approaches

There is little available data on the pharmacological treatment of PTSD in children and adolescents. It has barely been studied, and usually as an adjunct to psychosocial treatments (Terr, 1996). Still, it is being increasingly recognized as part of a multidimensional treatment approach to PTSD in adults (Sutherland & Davidson, 1994). As discussed above, PTSD is a disorder of various symptoms including severe anxiety, dissociation and disorganization, depression, and anger, and with potential underlying neurobiological mechanisms. As such, pharmacological treatment in children cannot be ruled out.

A variety of pharmacological agents have been used in the treatment of adults with PTSD to varying degrees of success including: tricyclic antidepressants (TCAs); monoamine oxidase inhibitors (MAOIs; phenelzine); selective serotenergic reuptake inhibitors (SSRIs; fluoxetine, sertraline, and fluvoxamine); anticonvulsant agents (carbamazepine and valproic acid); benzodiazepines (aprazolam, clonazepam, lorazepam); clonidine; and beta-blockers (propranolol). While inferring from adult studies that such agents would be appropriate with children or effective is not possible, a brief discussion on this topic is instructive. In several controlled trials with adult PTSD patients (Davidson et al., 1990; Frank, Kosten, Giller, & Dan, 1988; Shestatzky, Greenberg, & Lerer, 1988), drugs with serotonergic action (TCAs, MAOIs, and SSRIs) have achieved the most positive effects with the best results achieved after longer treatment trials (Sutherland & Davidson, 1994). TCAs and SSRIs are often prescribed for children with severe anxiety and depressive reactions and their potential use with children and adolescents with PTSD should be explored.

Again, as discussed above, many of the symptoms of PTSD have been hypothesized to result from excessive activity of the central adregeneric system, leading some clinicians to use adrenergic blocking agents such as propranolol and clonidine (Sutherland & Davidson, 1994). In one of the few studies to directly approach this issue in children, Kinzie and Leung (1989) found that clonidine (a centrally acting drug sometimes used for treatment of Tourette's syndrome) may help children who have significant avoidant symptoms, startle responses, or trauma-related depression. Pynoos and Nader (1993) note preliminary results suggesting that clonidine may reduce persistent arousal in children. In an uncontrolled, nonblind study, Famularo, Küscheff, & Fenton, (1988) found that propranolol (a β-blocking agent) relieved the arousal symptoms of children who were exposed to sexual assault. The results of these studies are consistent with previous trials of clonidine and propranolol in adult combat veterans (see Kolb, Burris, & Griffith, 1984).

While carefully controlled drug-treatment trials in children and adolescents with PTSD are awaited, use of pharmacological agents shows some promise. While many psychologists express an appropriate level of caution (if not aversion) when considering referral of children for pharmacological treatment, the presence of chronic and severely debilitating symptoms of PTSD in a child may require thoughtful consideration of pharmacotherapy.

Still, some precautions are worth mentioning here. First, Lundin (1994) has suggested that drugs be chosen carefully so that they do not undermine the individual's capacity for working through the trauma. Thus, he suggests that making regular use of benzodiazepines is generally inadvisable. Second, the issue of comorbid diagnoses should be evaluated thoroughly as some agents may be useful for targeting particular PTSD symptoms but may affect certain comorbid conditions. Finally, as noted by Sutherland and Davidson (1994) in their review of the literature, response to pharmacotherapy in PTSD may be relatively slow, perhaps reflecting underlying structural changes in the brain, and trials of eight weeks or longer may be necessary to achieve the maximum benefits.

5.16.4.3 Efficacy

There have been no randomized, controlled treatment trials for PTSD in children, and no long-term treatment follow up studies. However, regarding debriefing, Yule (1992) observed that children who attended debriefing meetings fared better on a range of outcome measures than children who were not offered such help. Inferences drawn from this study must be limited, however, since the debriefing group also received additional treatment. Stallard and Law's (1993) uncontrolled trial of debriefing showed significant improvements on standardized self-report measures in a small group of young children involved in a road traffic accident.

Galante and Foa's (1986) evaluation of structured group therapy showed significant teacher-rated improvements on the Rutter Questionnaire (Rutter, 1967) in children from one earthquake-affected village. By comparison, in only one out of five affected villages where therapeutic groups were not held did children improve significantly. Concerning individual therapy, Saigh's series (1987a, 1987b, 1989a, 1989b) of single case multiple baseline across traumatic scene studies is promising for behaviorally based exposure treatments. In an uncontrolled trial of individual cognitive behavior therapy with 19 sexually abused and traumatized children, Deblinger, McLeer, & Henry (1990) found that all symptoms showed some improvement: each major category of PTSD symptoms improved, and although some children were still symptomatic, none met criteria post-treatment.

5.16.5 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

The study of post-traumatic stress reactions in children remains wide open with regard to areas in need of additional research. Five main areas appear particularly important for the area of child traumatic stress: (i) descriptive studies of young people's reactions across trauma types and age/developmental stages; (ii) neurobiological correlates of PTSD; (iii) neuropsychological and physiological assessment of PTSD; (iv) follow-up studies of children with PTSD; and (v) response to psychological and pharmacological treatment.

The paucity of data available looking at post-traumatic reactions at different age levels has been highlighted. While PTSD can be diagnosed even in very young children, it is inaccurate to assume that PTSD, as currently defined, is sufficient to capture the breadth of children's post-traumatic reactions. Additional research using age-appropriate measures and standardized behavioral observation methods are needed. Furthermore, children's post-traumatic perceptions of the trauma, themselves, and their world have yet to be evaluated in any systematic fashion. The adaptation of belief scales based on the work of Janoff-Bulman (1992) to children may be useful in this regard.

The neurobiological models of PTSD have not been rigorously tested in children. Studies employing the hormonal, neuronal, and brain-imaging techniques used with adults need to be developed for use with children and adolescents. Similarly, psychophysiological measures have only been used in the 1990s with children, however, with promising findings (cf., Pynoos et al., 1993). Additional studies employing salivary cortisol tests and ambulatory measures of hyperarousal may be of particular use in this regard. Moreover, studies using neuropsychological measures developed with children to increase our understanding of the memory and concentration impairments associated with PTSD in children are needed.

Finally, and perhaps most important, is the need for long-term follow-up and treatment studies of PTSD in children and adolescents. Studies employing both referred and nonreferred children with PTSD and carefully selected control groups are necessary before any firm conclusions about the chronicity of PTSD, and the effectiveness of currently available treatments, can be reached.

5.16.6 SUMMARY

In this chapter the literature on the nature and treatment of PTSD in children and adolescents has been highlighted. This literature is growing but clearly lags behind its adult counterpart. However, current research supports the conclusion that children and adolescents exposed to severe and life-threatening traumas can develop PTSD as well as other disorders.

While PTSD as a diagnostic category has significant limitations for capturing all the effects of trauma in both children and adults, it has proved a useful guideline for both clinical and research purposes. In particular, there is an emerging body of work suggesting that across cultures and traumatic events, children exhibit similar types of stress reactions, which may reflect post-traumatic changes in the central nervous system as well as emotional and cognitive disturbances. Unfortunately, our understanding of the effects of trauma at different ages and their chronicity remains poor, and like other areas of child psychopathology, controlled treatment-outcome studies of childhood PTSD are desperately needed.

5.17.1 INTRODUCTION

It can be estimated that depression affects onwards of two million children and adolescents in the USA and Canada. As an internalizing disorder in young people it is a source of intense misery and distress to those affected. By its nature, depression is often a silent disorder that generally affects few persons other than the depressed youngster. Because of its internalizing nature, we may view depression as an insidious psychological disturbance in young people. Thus, for some youngsters depression may be inconspicuous yet have deleterious effects on the child.

Depression is a disorder and disturbance of mood that has been described from ancient times with continued efforts to clarify the nature of this aspect of the human condition. Although we no longer ascribe the etiology of depression, or melancholia, to the function of bodily humors such as black bile or "perturbations of the soul" (Jackson, 1986), there are many commonalties between ancient and contemporary descriptions of the phenomenology of depression. In the early part of the twentieth century, a number of psychoanalysts sought to explain depression in light of the prominent analytic theories of the time, as seen in the work of Karl Abraham, Sigmund Freud, Sandor Rado and, somewhat later, Melanie Klein. Although not specific to depression, of particular note is the pioneer work of Adolf Meyer, whose formulations of psychopathology may be seen as approximating a biopsychosocial perspective.

More recently, the study of depression has encompassed many diverse fields of scientific inquiry. Psychology and psychiatry are those fields that typically come to mind, but a wide-ranging review of the fields that have examined depression include: biochemistry, genetics, social work, nursing, counseling, business, epidemiology, pharmacology, neurology, pediatrics, general medicine, biology, zoology, sociology, education, physiology, endocrinology, and other disciplines. There are well over 1000 research and clinical articles on depression in children and adolescents that have been published in English language journals, with hundreds of new studies appearing each year. The range of investigations and domains covers a vast spectrum of the biopsychosocial sciences, from research on the activity of killer cells in depressed adolescents and the relationship between killer cell activity and severity of self-reported depression to studies of maternal attachment behavior and depressive affect in preschool children.

As described in this chapter, the wide range of scientific disciplines that have focused on depression in children and adolescents supports an integrated perspective for the understanding of this disorder in young people. This perspective may be illustrated by a biopsychosocial model of depression. The biopsychosocial model provides a platform or framework for exploring the nature and enhancing our understanding of depression by examining the complex interplay between the biological endowment and characteristics of the individual, the person's psychological competence, and the psychosocial stressors that may affect the individual. The biopsychosocial perspective is not unique to the study of depression and has been applied to a wide range of human conditions and problems.

5.17.1.1 Depression as an Internalizing Disorder

In the conceptualization of psychopathology in children and adolescents, a predominant theme over the past two decades has been the differentiation of disorders as a function of their general phenotypic expression. This has lead to the categorization of disorders as primarily internalizing or externalizing, based on their general symptom manifestation (Reynolds, 1992a). Internalizing disorders are those that tend to be composed of relative covert symptoms, many of which are cognitive, internal to the youngster, or relatively difficult to observe. Externalizing disorders are overt, highly observable either directly or indirectly (such as in the outcome of certain antisocial behaviors), and typically expressed as behavioral excess.

Depression and depressive (mood) disorders in children and adolescents may be viewed as internalizing disorders. Depression as a psychological disorder is replete with symptom characteristics that are internal to the individual. These features include symptoms of cognitive, emotional, behavioral, and physiological impairment or dysfunction. Depression is more than just a low or dysphoric mood such as feeling sad, blue, or down in the dumps. Depression typically affects multiple areas of individual functioning, including behavioral, emotional, somatic, and cognitive domains. Depressive disorders represent serious forms of psychopathology of childhood and adolescence, given that some depressive episodes may lead to potentially life-threatening or negative outcomes. Previous notions of "adolescent turmoil" or the perspective of the adolescent who is "just going through a moody stage" are no longer viable conceptualizations (Offer & Schonert-Reichl, 1992). This is amply evident when one considers the large numbers of depressed and suicidal youth, a significant number of whom do not survive to adulthood or do so with significantly reduced psychosocial competence or functioning.

Overt behavior problems in youngsters have typically been characterized by disorders of behavioral excesses, and as such are often viewed as externalizing problems. Externalizing disorders, such as conduct disorders and attention-deficit hyperactivity disorder, represent classes of disorders that frequently come to the attention of classroom teachers or parents. Symptoms of these disorders are typically represented by behavioral excesses that interfere with normal classroom behavior or social interactions. Contrary to this, internalizing disorders such as depression are often undetected due to the more covert nature of their symptoms. For instance, feelings of subjective misery, hopelessness, fatigue, anhedonia, difficulty sleeping, and other symptoms of depression may not be readily observable, particularly in youngsters who may be characterized as shy or somewhat withdrawn. Depression differs from other behavior disorders of childhood and adolescence in its comorbidity with suicidal risk.

5.17.1.2 Depression as a Problem in Children and Adolescents

Depression in children and adolescents, within the scope of current nomenclature and systems of classification, is considered to be a mood disorder similar in many respects to this disorder in adults. From another perspective, depression in children and adolescents may be considered as significant perturbation of mood. A depressed youngster may experience a range of symptoms, some of which may be overt, such as irritability or distinctly sad appearance, and others may be covert, as illustrated by feelings of low self-worth, hopelessness, suicidal thoughts, and guilt. In young people, depression represents a negative psychological state, that may be characterized as one of intense, subjective misery, despondency, and in some youngsters, irritability. Depression in children and adolescents can cause significant impairment in daily functioning and personal and social involvement (Puig-Antich et al., 1985). Children who are depressed are often withdrawn from the world around them, finding little pleasure in positive events or settings. Treats and previously fun activities are no longer desirable or sufficient to lighten their spirits. In young children, this affective state may be characterized as being moody or distant from others and slow to respond to social interactions with peers and family. Adolescents who are depressed often feel alone, helpless, and frustrated with friends and family who do not seem to understand them. Although this may characterize a great many adolescents, the depth and quality of these characteristics in depressed adolescents, and in particular, their lack of positive response to previously reinforcing events or activities generally distinguishes depression in adolescents from more normative trials and tribulations associated with the normative course of adolescence.

Some children and adolescents who are depressed also manifest suicidal thoughts and behaviors. This is particularly problematic and in some cases leads to death or physically disabling outcomes. Epidemiological data suggests that suicidal behaviors are a serious problem among children and adolescents (Reynolds & Mazza, 1994). Although some youngsters who demonstrate suicidal thoughts and behaviors do not manifest clinical levels of depression, the majority of suicidal youngsters are depressed, with many who view suicide as a way of ending their intense psychological distress.

Depression can take a variety of courses and chronocity, with relapse and recurrence relatively common over the lifespan (Keller, 1994; Kovacs, 1996a). Kovacs and colleagues, in a noteworthy longitudinal study of depression in children, found that for some youngsters, particularly those with a dysthymic disorder, their depression may last for many years, and in some children represents a precursor or risk factor for other psychiatric disorders (Kovacs, 1985; 1996b; Kovacs, Feinberg, Crouse-Novak, Paulauskas, Pollock, & Finkelstein, 1984a). Similarly, in a retrospective study of children who attended the Maudsley Hospital in London, UK, Harrington, Fudge, Rutter, Pickles, and Hill (1990) investigated the adult psychiatric status of 52 participants who initially demonstrated a significant number of depressive symptoms and 52 matched nonpsychiatric controls. They found that 40% of the childhood depressed group met Research Diagnostic Criteria (Spitzer, Endicott, & Robins, 1978) for depression within five years of entering adulthood, with 58% demonstrating a history of an affective disorder at the time of follow-up compared to 25% of the control sample. These investigations suggest that depression in children and adolescents may have long-term negative consequences.

Wamboldt (1994) examined the nature of medical and psychiatric disorders reported in child and adolescent patients seen at nine medical-psychiatric settings that are considered Type III or IV (moderate to severe medical and psychiatric problem treatment) child and adolescent medical-psychiatric units in the USA. With regard to psychiatric disorders, Wamboldt found a greater prevalence of internalizing disorders than externalizing disorders, with 32% of the patients demonstrating mood disorders, primarily depression. These data are based on a sample of 768 youngsters admitted during 1991 and who manifested both medical and psychiatric problems.

A number of studies suggest what appears to be a secular trend in the age of onset of depressive disorders in children and adolescents, with first episodes of depression found in increasingly younger children (Kovacs & Gatsonis, 1994; Lewinsohn, Rohde, Seeley, & Fisher, 1993). This is a significant point of concern and buttresses the need to recognize depression in young people at early stages and provide intervention or prevention.

5.17.1.3 Contemporary Interest

Contemporary interest in the study of depression in children and adolescents began in the late 1970s and early 1980s. Prior to this, the predominant perspectives in the literature were that depression in children was: nonexistent, masked, or expressed in symptoms that were significantly different from those found in depressed adults (Reynolds, 1985). Depression in children was also conceptualized by the construct of depressive equivalents (Glaser, 1967; Hollon, 1970). In this manner, depression in children was inferred by overt, negative behaviors such as acting-out, aggression, hyperactivity, and delinquency, as well as psychosomatic and hypochondriacal disorders (Lesse, 1981). Some exceptions to these perspectives were postulated (e.g., Sandler & Jaffe, 1965) although for a number of reasons, did not significantly influence the existing status of depression in childhood (Bemporad, 1994).

Early research and clinical interest in depression in children and adolescents also focused on bipolar disorder. This was generally seen as an early onset of a typically adult disorder. The extreme nature of symptoms in manic depressive illness and mania, and the similarity between symptoms of these disorders in children and adolescents to those found in adults, led to a number of clinical reports (e.g., Beres & Alpert, 1940; Campbell, 1952). Carlson (1994) notes that Kraepelin in 1921 was one of the first to describe manic depressive illness in a child. However, research reports on manic depressive illness in children and adolescents are scarce before the 1970s.

In the 1970s, a small but significant number of clinical and research reports appeared that suggested the importance of studying depression in young people. An important article that shed light on the existence of depression in childhood was published in 1970 by Pozanaski and Zrull who described clinical cases gleaned from the outpatient files of the Children's Psychiatric Hospital at the University of Michigan Medical Center from the years 1964 to 1968. Based upon an examination of records of 1788 children, 98 cases were identified that showed significant evidence of depression, with 14 cases providing sufficient file data for in-depth examination and reporting. Children ranged in age from 3 to 12 years. Primary symptoms of depression in these youngsters included: sad, unhappy, depressed appearance; withdrawal; expressed feelings of rejection and being unloved; and autoerotic behavior. Poor self-image and self-worth were predominant as a depressive symptom.

Weinberg and his colleagues are frequently associated with the development of the first contemporary diagnostic criteria for depression in children (Ling, Oftedal, & Weinberg, 1970; Weinberg, Rutman, Sullivan, Penick, & Dietz, 1973). The Weinberg criteria were an outcome of the observation of depressive symptoms in children that were phenomenologically similar to symptoms of the disorder as specified for adults. An examination of the symptoms and criteria delineated by Weinberg et al. (1973) shows a great deal of communality with contemporary diagnostic formulations. In the late 1970s, Petti (1978) developed the Bellevue Index of Depression (BID), a semistructured clinical interview of depression designed for use with children based on Weinberg symptomatology.

In the early 1980s researchers also began to test the viability of unique conceptualizations of depression in childhood. Christ, Adler, Isacoff, and Gershansky (1981) investigated the concept of masked depression by examining clinical records of over 10 000 psychiatrically hospitalized children and adolescents. They compared diagnoses of depression (psychotic and neurotic) with: symptoms of depression (suicidal behavior, sleep disturbance, appetite changes, fatigue, etc.) specified by contemporary classification systems; and hypothesized masked features of depression as indicated by serious aggression and misbehavior. The authors found that youngsters with a diagnosis of a depressive disorder demonstrated greater numbers of contemporary symptoms of depression, while masked features were negatively related to this diagnosis, and occurred at a lower frequency in depressed youngsters as compared to youngsters with other psychopathology.

Around this time period, a number of reports began to emerge as to the clinical use of adult antidepressant medications with children. Antidepressant medications were relatively new but, within 10 years of early reports with adults, Frommer (1967) described the use of antidepressants with children. Additional reports by Kuhn and Kuhn (1971) and Stack (1971), among others, soon followed.

In 1980, the American Psychiatric Association (APA) published the third edition of the *Diagnostic and statistical manual of mental disorders* (*DSM-III*; APA 1980). Depressive (mood) disorders where listed in the adult disorders section, differential symptom criteria and duration specifications for major depression and dysthymic disorder, respectively were provided for these disorders in children and adolescents as compared to the disorders in adults. The publication of *DSM-III*, as well as research findings such as those by Christ et al. (1981), led to a focus on symptoms of depression in children and adolescents as similar in many regards to adults.

The acceptance of the largely adult specifications for depression in the *DSM* is not universal nor, as suggested by Nurcombe and colleagues (Nurcombe, 1994; Nurcombe et al., 1989), strongly supported by research evidence. Nurcombe (1994) examined the validity of major depression as a diagnosis in children and adolescents using as criteria: natural history, psychobiological markers, genetic studies, response to treatment, and construct validity. The last was based on multivariate analyses of various checklists and measures. As presented, much of the evidence is mixed, suggesting that depressive disorders in children may not be as currently defined by *DSM* with more work needed for the presentation of diagnostic validity of the disorder.

Based on diagnostic and epidemiological surveys of children and adolescents it is evident that depression is a significant problem among youngsters (Reynolds & Johnston, 1994). Epidemiological studies suggest that between 3% and 5% of children and 7–10% of adolescents manifest clinical levels of depression (Fleming & Offord, 1990; Lewinsohn, Hops, Roberts, Seeley, & Andrews, 1993; Poznanski & Mokros, 1994; Whitaker et al., 1990), with lifetime rates in young people significantly higher (Lewinsohn et al., 1993). These data, and the general undertreatment of depression in children and adolescents (Keller, Lavori, Beardslee, Wunder, & Ryan, 1991) point to the critical need for study, identification, and treatment of depression in young people.

5.17.2 BIOPSYCHOSOCIAL MODEL OF DEPRESSION IN CHILDREN AND ADOLESCENTS

In psychiatry, the biopsychosocial perspective represents a shift from a biomedical model, with its focus primarily on the biology of disease or disorders, to one of integration of psychological and dynamic characteristics, social and environmental forces, and biological bases. The biopsychosocial model is useful for the study and understanding of depression in children and adolescents, as well as adults. The biopsychosocial perspective has also been applied to numerous other aspects of human behavior and disorders (Paris, 1994; Shalev, 1993).

The psychobiological approach to the study of human behavior and problems has a long history (Dewsbury, 1991), and is illustrated in its earlier presentation by the integrated, commonsense perspective of Adolf Meyer. Meyer's perspective of psychiatric disturbance as due in part to, or exacerbated by environmental causes, can be viewed as a precursor to the current biopsychosocial perspective. Meyer's integrated approach to psychiatry, which he called psychobiology (Meyer, 1957), was also interactive, in that psychiatric illness was viewed as an interaction (or reaction) between the psychobiological and life stressors. Likewise, the biobehavioral model of depression proposed by Akiskal (1979) is consistent with this perspective and integrates biological, psychosocial, developmental, and environmental stressors as a basis for the development of depression.

The biopsychosocial model for the provision of general medical services was espoused by

Engel (1978, 1980). Presented as a systems approach in which the person does not exist in isolation, the biopsychosocial model was proposed in part to deal with the general over-reliance of physicians on the biomedical model in which the focus was on disease with limited concern about the patient as a person. In this manner, the biopsychosocial model or perspective is similar in its general focus to the approach of Meyer in psychiatry, and provides a useful heuristic for developing an understanding of depression in children and adolescents.

The biopsychosocial perspective, although not extensively practiced, has been a relatively popular concept within the psychiatric treatment literature because it suggests an integrated systems approach for therapy. Karasu (1990) in his comparison and integration of models of psychotherapy (dynamic, cognitive, and interpersonal) for depression, has provided suggestions for the indication of pharmacotherapy, psychotherapy, or their combination for the treatment of this disorder. The combinatory approach to treatment conforms to the "biopsychological perspective" of childhood depression described by Kashani and Cantwell (1983).

The basic applications of this perspective are not new to the study of depression in children and adolescents. Lewis and Lewis (1979) described a psychobiological perspective on depression that recognized psychoanalytic, genetic, and biochemical bases for the development and subsequent treatment of depression in children. Vasile et al. (1987) described a "biopsychosocial approach" for treating persons with depression that implements a consultation model for the evaluation and recommendation of psychological, pharmacological, or combined therapies. Although specific to adults, this integrative and evaluative approach appears useful for the treatment of depressed children and adolescents.

The biopsychosocial model of depression delineated by Reynolds (1997a) and briefly described below provides a perspective for understanding depression in children and adolescents as well as a framework for intervention and the provision of services. Within this model, biological, as well as psychosocial, factors play a role in child and adolescent depression. In some cases, there is a greater emphasis exerted by either the biological or psychosocial, indicating a primary modality for treatment of the disorder. However, the interactive nature of the model suggests that multimodal treatments may show the greatest efficacy, both in initial treatment gains and potential reduction of reoccurrence.

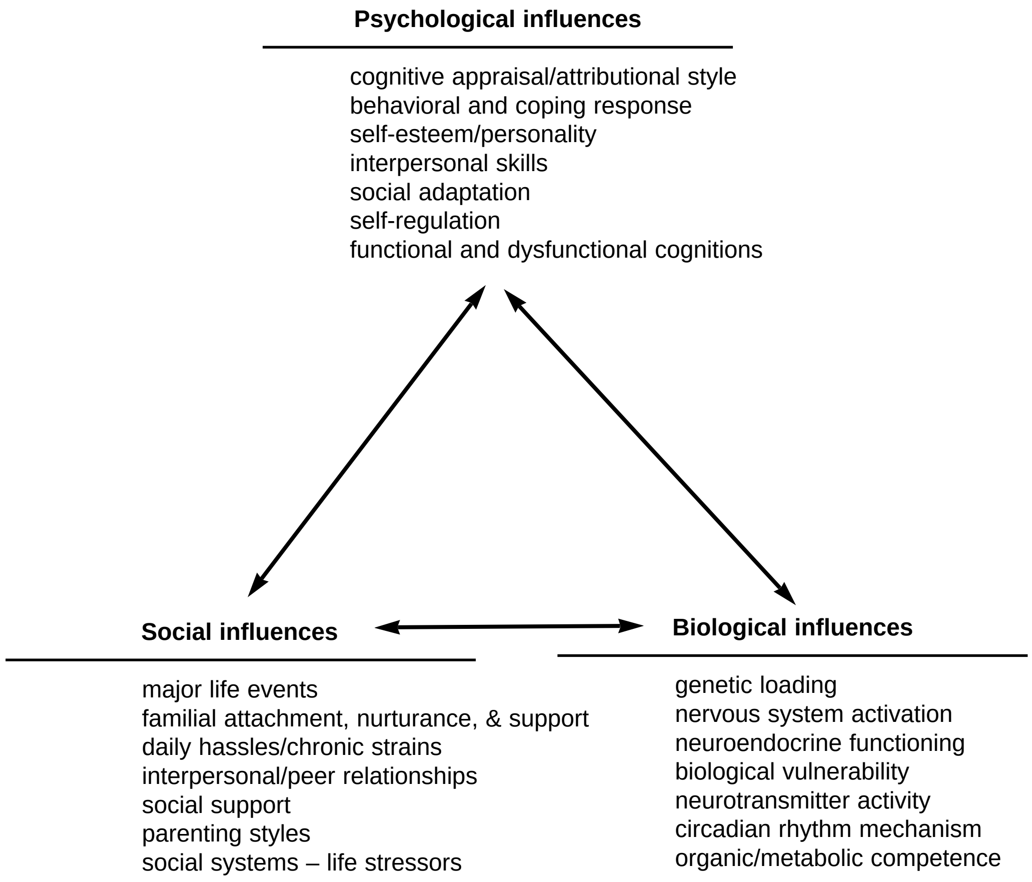
5.17.2.1 Tripartite Model

The biopsychosocial perspective on depression in children and adolescents may be represented as a tripartite dynamic model (Reynolds, 1997a). This model is illustrated in Figure 1. Similar to the model of reciprocal determinism postulated by Bandura (1978) for understanding human behavior, the biopsychosocial prospective (described below) considers reciprocal pathways. The strength of these pathways in the pathogenesis, maintenance, or exacerbation of depression or depressive disorders may vary as function of developmental level, individual strengths and deficits within each domain, nature of the reciprocal interactions, and the nature of the depressive outcome.

In the model, biological, psychological, and social–environmental attributes and influences are closely intertwined with intersecting pathways unique to each individual. Given the myriad combinations and interactions, the untangling of these main effects, interactions, and reciprocal paths for an individual is well beyond the scope of current science and practice. However, it is likely that, with sufficient scrutiny, major sources and some level of interactions across the three primary domains can be investigated to gain insight into the nature, potential etiology, exacerbating and maintaining factors, and the possible course and outcome of the individual's affective status.

Two aspects that are not depicted, yet which are critical, are that this model is dynamic and developmental. There is evidence to infer that depression in children is, in a number of respects, different from depression in adults, although there are probably more communalities than differences. There is also the likelihood that some differences are not specific to diagnostic symptomatology, but in its internal structure. Likewise, there are a number of possible developmental trajectories that may relate to differences in the nature as well as expression of depression in youngsters as compared to adults. It may be that biological components of depression become more pronounced as the human organism matures. This may be most evident in findings from neuroendocrine research that has focused on the relationship between hypothalamic–pituitary–adrenal axis function and depression in children (Puig-Antich et al., 1989). Overall, research examining neurobiological correlates in depressed children compared to adults has been mixed (Emslie, Weinberg, Kennard, & Kowatch, 1994).

The psychological domain includes cognitive and behavioral competencies and deficits that are linked to the ontogenesis of depression. As



Psychological influences
cognitive appraisal/attributional style
behavioral and coping response
self-esteem/personality
interpersonal skills
social adaptation
self-regulation
functional and dysfunctional cognitions
Social influences
major life events
familial attachment, nurturance, & support
daily hassles/chronic strains
interpersonal/peer relationships
social support
parenting styles
social systems – life stressors
Biological influences
genetic loading
nervous system activation
neuroendocrine functioning
biological vulnerability
neurotransmitter activity
circadian rhythm mechanism
organic/metabolic competence

Figure 1 Biopsychosocial model of depression (Reynolds, 1997a).

models of depression suggest, these components do not act in isolation, but are set in motion by the experience of socio-environmental factors, such as stress, nurturance, and attachment, along with a biological propensity or interaction. However, the cognitive and behavioral/coping functioning of the individual will determine to some extent the impact of the social system (i.e., interpersonal stressors, minor/major life event, etc.) on affective competence and biological/neuroendocrine response/interaction. Likewise, dysfunctional cognitions and behavioral response can be a function of neuroendocrine influences (Wright & Thase, 1992).

Magnusson (1985) has described an interactional paradigm for examining aspects of human functioning that integrates psychology and biology as important person factors in examining person by environment interactions and is consistent with the biopsychosocial perspective. As such, a longitudinal approach is needed to understand the mechanism of human behavior. In this regard, development plays a critical role in the biopsychosocial perspective and can be considered to be an important component of psychology, biology, and the social domain. Magnusson and colleagues (Magnusson & Torestad, 1993; Stattin & Magnusson, 1989) have delineated this interactional approach with a major focus on the developmental and biological nature of person, and in particular adolescent and environment interactions, cumulating in the description of a holistic, dynamic model of personality. This approach also has utility for the study and understanding of depression in young people.

5.17.2.2 Biopsychosocial Domains and Interactions

The biopsychosocial model presented in Figure 1 is a simplified representation of the primary domains and their potential interactions. In reality, the level of interactions of both direct and indirect effects of individual components within and between domains is, in most situations, quite complex and, given the potential numbers and measurability of these variables, is beyond the scope of most research investigations. Remschmidt (1992) notes that the interactions between biological and psychosocial variables that influence the development of psychopathology in children and adolescents may be multiplicative as well as additive.

It is important to recognize that both strengths and weaknesses may be present within each domain. Thus, a youngster may show a deficit in the interpersonal skills domain as a psychological influence, or may demonstrate competence in interpersonal skills that may reduce vulnerability for depression. In a similar vein, personality may enhance psychological resilience or act as a factor that exacerbates biological or social–environmental events. Likewise, biological competence may provide a protective factor for adverse or stressful major life events.

Within the scope of this chapter it is not possible to provide delineation of the main effects of factors associated with the biological, psychological, and social–environmental domains, and the researched interactions between these domains and depression in children and adolescents. Research shows that all three domains play a role in the manifestation of depression in children and adolescents. Described below are a few examples of each domain of the model.

5.17.2.2.1 Biological influences

Biological bases of depressive disorders have been extensively examined in adults and to a more limited extent children and adolescents (Emslie et al. 1994). Domains of inquiry range from brain neurochemistry, such as serotonin mechanism, adrenal-hyper-cortical functioning and activity, and sleep architecture to genetics. Also included in this research domain is the study of antidepressants. For example, a great deal of research in psychiatry has focused on serotonergic mechanisms, specifically the role of serotonin (5-HT) in the regulation of psychological and biological functioning. This research has had a major impact on the development of new classes of pharmacological agents for the treatment of depression, such as antidepressant medications that are selective in their serotonin reuptake properties. These latter agents include such drugs as fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil). Within the model, biology affects as well as interacts with psychosocial factors to increase vulnerability for the development of maladaptive psychological processes and adaptation.

Likewise, a great deal of interest and research has focused the hypothalamic–pituitary–adrenocortical (HPA) axis as a biological focal point in the environmental stress–depressive response pathway. A number of biological systems and factors, such as prolactin, growth hormone, melatonin metabolism, sleep, and neurotransmitter activity have been linked as of potential etiological relevance to depression (Leibenluft, Fiero, & Rubinow, 1994). There is also evidence to suggest a genetic loading for various depressive disorders, such as major depression and bipolar disorder, with bipolar disorder having the greater genetic component (Herdman, Gough, Liskowski, & Hall, 1995).

5.17.2.2.2 Psychological influences

The domain of psychological influences may best be described as the psychological characteristics, both strengths and weaknesses, as well as vulnerabilities that make up the youngster's emotional and mental health competence. In Figure 1 a number of individual characteristics are listed to provide a general description of this domain. In reality, there are many other psychological influences, some of which are well defined by research and theory, and others that are less well defined or understood. These factors may be either protective or risk factors.

A number of cognitive and behavioral processes are particularly relevant to the understanding of the development of depression. Some of these components are linked to theories of depression. For example, the role of self-regulation (Kanfer, 1970) as it relates to problems in self-control (self-monitoring, self-evaluation, self-reinforcement) has been postulated by Rehm (1977) as model of depression. Problems or deficits in cognitive appraisal, maladaptive behavioral response to reinforcement, dysfunctional cognitions, and erroneous attributional style have been identified by various contemporary theories and models as linked to the development of depression (Abramson, Seligman, & Teasdale, 1978; Beck, 1967; Ellis, 1962; Lewinsohn, 1975).

5.17.2.2.3 Social influences

The social component represents the social–environmental domain and by its nature includes a very wide range of influences. Included here are: stressful events, including major negative life events as well as daily hassles and chronic strains; parental influences, including attachment, nurturance, marital discord, support, and parenting style; social support; peer and interpersonal relationships; and a host of social and environmental influences such as exposure to violence, victimization, maltreatment, social disadvantage, peer and social pressures, and school and work stress among others.

As an example, parental nurturance is a broad domain that includes parenting behavior such as the nature and use of discipline (e.g., consistent/inconsistent, reasonable/harsh, etc.); communication style; over/under controlling; parental warmth; and other behaviors, characteristics, and competencies. Straus and Kantor (1994), in a retrospective study of adults queried as to having received corporal punishment during their teen years, found that corporal punishment was significantly related to increased risk for depression, even when controlling for factors such as socioeconomic status (SES), gender, age, and parental marital violence. Oakley-Browne et al. (1995) also found that adverse parenting in childhood had an increased risk for depression in adulthood. It is also important to note that, during adolescence, there is often a transition in the relationship that youngsters have with parents and peers, with peers becoming increasingly important as a source for support and attitude development.

5.17.2.3 Summary

In the biopsychosocial model, the three primary domains (biology, psychology, and social) interact to produce depression in persons. The nature, course, severity, treatment viability, and other characteristics of depression in young people as well as adults is a function of the nature of the interactions and the domain-specific characteristics and vulnerabilities. This model is also reciprocal, in that factors within the domains may interact as well as affect other domains in a reciprocal manner.

For example, some psychosocial stressors have been noted to be responsible for suppressed T-lymphocyte function (Brosschot et al., 1994; Syvalahti, 1987) and a host of hormonal changes. Such abnormalities in immune function and endocrine changes can increase vulnerability to depression. In adolescents, major negative life events have been linked to reduced immune function and neuroendocrine changes (Birmaher et al., 1994).

As the interactional approach may suggest, it is virtually impossible to separate out the variances associated with any one domain, given the potential complexities of the interactions within as well as between domains. However, researchers are beginning to recognize the multivariate nature of these domains as a basis for the study of depression. In a study examining the prediction of major depression in a sample of 1360 women (680 pairs of twins), Kendler, Kessler, Neale, Heath, and Eaves (1993) examined the main effects (both direct and indirect) of a number of biological (e.g., genetic), social (e.g., stressful life events), and psychological (e.g., neuroticism) factors.

The biopsychosocial model suggests there are multiple pathways to the development of depression in children and adolescents. From this perspective, psychological, social and biological models have validity but are individually insufficient to explain the range of etiologies associated with depression.

5.17.3 DIAGNOSTIC FORMULATIONS OF DEPRESSION IN CHILDREN AND ADOLESCENTS

The diagnosis of depression involves the evaluation and comparison of the characteristics and duration of an individual's symptoms with criteria and classification rules for one or more disorders. In this manner, diagnosis constitutes an assessment or measurement procedure. Thus, measurement error, or the reliability of the diagnosis is an important consideration. Sources of potential measurement error in making a diagnosis include error due to the informant, the diagnostic instrument (e.g., clinical interview), the diagnostician, as well as the classification system. In some respects, a diagnosis may be viewed as a hypothesis that represents "the clinician's best judgment" (Rush, 1990, p. 5) of the individual's condition. Research suggests that the diagnosis of psychopathology and, more specifically, depressive disorders in children is not perfect (APA, 1980; Vitiello, Malone, Buschle, Delaney, & Behar, 1990). For the evaluation of depression in children and adolescents, diagnosis is one method with the outcome being a characterization of specific disorder or disorders based on a formal classification scheme. Other measurement procedures, such as the assessment of severity of depressive symptoms, either by clinical interview or self-report without comparison to a classification system, are often used in clinical and research applications with children and adolescents. The latter may be viewed as providing a focus on the assessment of depression as a syndrome rather than delineating categorically distinct depressive disorders. As noted by Nurcombe (1994), the perspective of depression as a syndrome is postulated on the specifications of symptoms and signs that are predominated by dysphoric mood.

The classification systems currently used in formulating psychiatric diagnoses are continually being refined. In this sense, such systems are not static, immutable, or complete in their description of inclusion and exclusion criteria for specific disorders. This iterative process is exemplified by ongoing revisions in the *DSM* by the APA and the *International statistical classification of diseases and related health problems* (*ICD*) by the World Health Organization (WHO, 1992). These are the primary but not the only systems or approaches to the classification of depressive disorders. It is also important to recognize that depressive symptoms may occur in a number of medical and neurological conditions (Klerman, 1987; Rush, 1990) that need to be considered in the diagnosis of a depressive disorder. Several systems that have been used to diagnose depression in children and adolescents are described below.

5.17.3.1 Systems and Approaches in the Diagnosis of Depression

There are a number of classification systems that have been developed or provide for the diagnosis of depressive disorders in children and adolescents. Most of the current systems are based on a taxonomic approach for the differentiation of type and subtypes of depressive disorders based on particular clusters of symptoms and symptom duration. In North America the primary system used for the classification of depressive disorders in children, adolescents, and adults is the *DSM-IV* (APA, 1994). The *DSM-IV* criteria for depression in children and adolescents are described in a later section.

For certain research applications, the Research Diagnostic Criteria (RDC), developed by Spitzer et al. (1978) is used for the diagnosis of depressive subtypes. The RDC provides greater specificity of subtypes of depression and may be evaluated using a formal diagnostic clinical interview, the Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978) for adults as well as adolescents, and the kiddie SADS for children (K-SADS; Puig-Antich & Chambers, 1978), which has also been used for adolescents (e.g., Lewinsohn, Rohde, & Seeley, 1995). These interview schedules are specific to the RDC in the diagnoses they provide, although research investigators have developed algorithms for deriving *DSM* diagnoses from SADS interviews.

As noted earlier, Poznanski and Zrull (1970) using a chart-review method, provided descriptions of clinical symptoms constituting depression in children. As such, these symptoms were viewed as a basis for the diagnosis of depression in youngsters, with the general premise being that depression as a disorder did manifest itself in childhood (Poznanski, Krahenbuhl, & Zrull, 1976, Poznanski & Zrull, 1970). Later, Poznanski and her colleagues (Poznanski, 1982; Poznanski, Mokros, Grossman, & Freeman, 1985) reformulated their clinical description of symptomatology for depression in children, and developed a clinical interview for the assessment of depression in children (Poznanski, Cook, & Carroll, 1979; Poznanski et al., 1984).

In the early 1970s, Weinberg and colleagues proposed a set of criteria for depression in children (Weinberg et al. 1973) with Weinberg and Brumback (1976) providing diagnostic criteria for mania in children. The Weinberg criteria for depression include (i) the presence of both dysphoric mood and self-deprecatory thoughts; (ii) two or more of: aggressive behavior, sleep disturbance, change in school performance, diminished socialization, change in attitude toward school, somatic complaints, loss of usually energy, and change in appetite and/or weight; and (iii) symptoms need to be present for more than one month and represent a change in the child's usual behavior. Although the Weinberg criteria are rarely used today, they are noteworthy for their early impact as well as their similarity to symptom specifications for current *DSM-IV* criteria for depressive disorders in young people.

5.17.3.2 *Diagnostic and Statistical Manual of Mental Disorders*

Depressive disorders in the *DSM-IV* fall under the category of mood disorders, and include major depression, bipolar disorders, cyclothymic disorder, and dysthymic disorder as primary mood disorders. Disorders are differentiated by specific clusters of symptoms, age of onset, and the duration of symptoms. Disorders that are most likely to be found in school-aged youngsters are major depression and dysthymia, although adjustment disorder with depressed mood is also diagnostically relevant. Bipolar disorders also demonstrate an onset during adolescence in a significant number of individuals who develop this disorder (Loranger & Levine, 1978; McGlashan, 1988). The depressive disorders subsumed under the domain of mood disorders in the *DSM-IV* and their associated course and subtype specifiers are presented in Table 1. It should also be noted that diagnostic categories of: mood disorder due to medical condition; substance-induced mood disorder; and mood disorder not otherwise specified may also be diagnosed in children and adolescents.

5.17.3.2.1 Major depressive disorder

Major depressive disorder (MDD) in *DSM-IV* is presented as a relatively severe, acute form of depression. Major depressive disorder may be classified as a single episode or recurrent, the

Table 1 *DSM-IV* Mood Disorders in Children and Adolescents.

- Major depressive disorder
  - single episode[1–6]
  - recurrent[1–8]
- Dysthymic disorder (early onset)[2]

- Bipolar disorder I
  - single manic episode[3,4,6]
  - most recent episode depressed[1–9]
  - most recent episode hypomanic[7–9]
  - most recent episode manic[3,4,6–9]
  - most recent episode mixed[3,4,6–9]
  - most recent episode unspecified[7–9]
- Bipolar disorder II
  - hypomanic[7–9]
  - depressed[1–9]
- Cyclothymic disorder
  - May also include:
    - [1] with melancholic features
    - [2] with atypical features
    - [3] with catatonic features
    - [4] with postpartum onset
    - [5] chronic
    - [6] severity/psychotic/remission specifiers
  - course specifiers:
    - [7] with seasonal pattern
    - [8] with rapid cycling
    - [9] with/without interepisode recovery

latter specifying a history of previous MDD episode(s). As a disorder, MDD is defined by the following criteria and symptomatology: the presence of five of the following symptoms, one of which is either dysphoric or irritable mood, or loss of interest or pleasure in all or almost all activities. The other symptoms include: sleep problems as manifested by insomnia or hypersomnia; complaints or other evidence of diminished ability to think, make decisions, or difficulty concentrating; loss of energy or general fatigue; eating problems as manifested by decreased or increased appetite or significant weight loss or gain (in young children failure to make expected weight gains is symptomatic); psychomotor retardation or agitation; suicidal or morbid ideation, death wishes, or suicide attempts; and feelings of self-reproach, worthlessness, or excessive or inappropriate guilt (which may be delusional). Symptoms need to be present nearly every day for a period of at least two weeks. Exclusion criteria are also specified that preclude a number of other pathologies, such as organic mental disorder and other etiologies (i.e., a normal response to bereavement) as concomitant problems, for a diagnosis of major depression. The *DSM-IV* provides information to assist the clinician in a differential diagnosis of major depression, as opposed to several conditions that may include significant depressive symptoms.

As shown in Table 1, major depression may be specified as a single episode (without a history of manic or hypomanic episode) or recurrent, the latter describing a history of two or more major depressive episodes separated by at least two months of normal functioning. There is also a range of additional features that may characterize the nature of the depressive episode, including: with melancholic features, catatonic features, atypical features, postpartum onset (adolescents), and indications of the severity (mild, moderate, severe), with or without psychotic features, and in partial or full remission. A seasonal pattern, often referred to as seasonal affective disorder, may be indicated.

5.17.3.2.2 Dysthymic disorder

In the *DSM-IV* dysthymic disorder represents a relatively chronic depressive disorder that is typically less severe in symptom distress than major depression, but typically of greater duration. Diagnostic criteria for dysthymic disorder in children and adolescents includes a depressed or irritable mood for most of the day, and manifested most of the time over a period of at least one year, although there may be periods of up to two months during which symptoms are not present. In addition to symptoms of depressed or irritable mood, at least two of the following symptoms must be present when depressed: appetite loss or gain, insomnia or hypersomnia, fatigue or low energy level, low self-esteem, difficulty concentrating or problems making decisions, and feelings of hopelessness. Exclusion criteria include: showing no evidence of major depressive episode during the initial year of the disorder; never having a manic or hypomanic episode; and not being superimposed on a chronic psychosis, or due to or maintained by an organic factor. Diagnostic criteria for dysthymia in children and adolescents differ from those for adults for whom symptoms of this disorder must be present for two years for a diagnosis.

5.17.3.2.3 Bipolar disorder

Bipolar disorder is a severe and typically long-term psychiatric condition that often represents a diagnostic challenge for clinicians. A number of researchers have noted the difficulties in this diagnosis as well as the propensity for misdiagnosis (Carlson, 1994; Joyce, 1984; Weller, Weller, Tucker, & Fristad, 1986). The essential feature of bipolar disorder is the occurrence of one or more episodes of mania or hypomania, typically with a history of one or more major depressive episodes. The *DSM-IV* delineates two forms of bipolar disorder, bipolar disorder I and bipolar disorder II, that differ as a function of the level of mania, with bipolar II associated with a hypomanic episode. Table 1 provides a description of the types of episodes of mania and depression associated with bipolar disorders. Of note is the mixed episode in which criteria for a manic episode and major depressive episode are present nearly every day with the youngster rapidly cycling between disorders. As noted in Table 1, bipolar disorder may also conform to a seasonal pattern.

The manic episode, which may last from one week to several months, is characterized by a clear-cut period of mood elevation, irritability, or expansiveness. In addition, three (or four if the manic episode is characterized by irritability) of the following symptoms must be present, including: grandiosity or inflated self-esteem, reduced need for sleep, more or excessively talkative, flights of ideas or perception that thoughts are racing, very distractible, increased time spent on goal-directed activities or psychomotor agitation, and overinvolvement in pleasurable, potentially risk-taking activities. Lastly, the overall clinical picture is sufficiently severe to cause impairment in functioning or require hospitalization. A somewhat milder variant that does not include the latter criteria of significant impairment in functioning nor delusions, is specified as a hypomanic episode.

5.17.3.2.4 Cyclothymic disorder

Cyclothymic disorder is a chronic mood disorder, symptomatically similar to bipolar disorder but of less severity. Cyclothymic disorder is analogous to dysthymic disorder in that depressive symptoms are not sufficient for a diagnosis of major depression, and the symptoms must be present for one year with periods of up to two months in which symptoms are not present. During the course of the disorder, there are numerous hypomanic episodes and periods of depressed mood or loss of interest or pleasure.

5.17.3.3 Alternatives to *DSM*: Clinical Severity, Subsyndromal Depression, and Depressive Symptoms

There have been a number of suggestions that criteria for *DSM* depressive disorders are too stringent and results in an underestimate of persons with significant levels of depressive symptoms. Thus, a person may show a level of depressive symptoms that is not sufficient to meet criteria for a *DSM* disorder yet, by its symptom severity level, may be considered clinically relevant and a valid target for intervention. Bland (1994) noted the problem of threshold in the use of *DSM*-specific criteria for diagnosis, in that a certain number of symptoms are required for a diagnosis and the patient who falls one symptom short of this does not receive a diagnosis, even when presenting symptoms are severe.

Gotlib, Lewinsohn, and Seeley (1995) found that youngsters who had clinically significant levels of depressive symptoms but did not meet criteria for major depression were twice as likely to develop a psychiatric disorder as compared to a nondepressed group, and also demonstrated significantly poorer psychosocial functioning than the nonsymptomatic group. Youngsters with clinically significant depressive symptoms were similar in psychosocial functioning to a comparison group of youngsters with major depression. These results suggest the clinical importance of attending to youngsters who may not meet criteria for major depression yet show significant levels of depressive symptomatology.

Judd, Rapoport, Paulus, and Brown (1994) examined depressive symptom data from the National Institute of Mental Health epidemiological catchment area (ECA) study and developed a clinical condition that they described as "subsyndromal symptomatic depression." Similarly, Horwath, Johnson, Klerman, and Weissman (1994) focused on ECA incidence data specific to persons who developed an episode of major depression over a one year interval between interviews. They found that persons with prior symptoms of depression or a dysthymic disorder were at relative risk for depression, with 50% of individuals who developed a major depressive episode demonstrating a history of depressive symptoms. The authors highlight the clinical importance of depressive symptoms by noting that "if depressive symptoms could be identified and treated before major depression first developed, many first onset cases of major depression could potentially be prevented" (p. 333), and that "measures designed to identify this group prior to the onset of major depression may represent an important step in primary prevention" (p. 333). Although the data from Judd et al. (1994) and Horwath et al. (1994) is specific to adults, it can be generalized to children and adolescents. Toward this end, a multiple-gate assessment procedure has been presented by Reynolds (1986a) for the identification of children and adolescents with significant clinical levels of depressive symptomatology.

In the diagnostic classification of mood disorders in the WHO *ICD-10*, a depressive episode may be classified as a severe depressive episode or a mild depressive episode, the latter different from dysthymia. However, in the worldwide field trials of the *ICD-10*, relative low interrater agreement was found for the mild depressive episode (code F31.1) as well as dysthymia (F34.1) (Sartorius et al. 1993). Sartorius et al. suggest that clinicians had difficulty distinguishing between dysthymia and mild depressive episode and recurrent mild depressive disorder (F33.1), as well as generalized anxiety disorder (F41.1), mixed anxiety and depressive disorder (F41.2) and adjustment disorder (F43.2). It is also useful to note that although interrater reliability for these disorders was low for the worldwide field trials, interrater agreement was even lower for field trials in the USA and Canada (Regier, Kaelber, Roper, Rae, & Sartorius, 1994). Although these data are based on adult samples, it does demonstrate that our diagnostic formulations of depressive disorders are still in a state of evolution.

5.17.4 ASSESSMENT OF DEPRESSION IN CHILDREN AND ADOLESCENTS

Assessment is a procedure basic to the identification of depression in children and adolescents for clinical purposes, as well as for use in the study of biological, social, and psychological characteristics; sequaele; outcome; determination of treatment efficacy; and other research applications. There are two primary categories of assessment measures: those designed for obtaining a diagnosis, and measures developed to evaluate the severity of depressive symptomatology. Although diagnostic measures may provide severity scores, their primary utilization is as diagnostic tools. In general clinical practice and in a multitude of research applications, the assessment of depression in children and adolescents is typically accomplished using self-report severity measures or clinical interviews, the latter including diagnostic measures and severity measures. Reports by significant others such as parents, teachers, and peers have been used to a limited extent and are not discussed in this chapter. Readers interested in assessment of depression via reports of others, as well as the issue of informant variability, are directed to Clarizio (1994) and Kazdin (1994).

There are several characteristics of depression that support the use of self-report assessment procedures, given linguistic and metacognitive competence in the child. Depression as an internalizing disorder includes primary symptoms that are internal to the youngster and are not easily observable. Cognitive symptoms of guilt, self-deprecation, suicidal ideation, hopelessness, and feelings of worthlessness are depressive symptoms that are subjective to the child. Some vegetative symptoms such as insomnia, appetite loss, and other problems are sometimes difficult for others to observe and may go undetected by parents and significant others.

This chapter presents information on several self-report measures of depression for children and adolescents. Although a number of structured and semistructured clinical interviews exist, the application of these interviews is generally limited to various research investigations. The primary tools used in the clinical assessment of depression in children and adolescents in clinical and school settings are self-report measures. Diagnostic interviews are briefly noted below and several semistructured clinical interviews that provide for the assessment of the severity of depressive symptomatology in children and adolescents are described.

The manner in which we assess depression in youngsters guides how we organize our perspective of depressive phenomena. For the determination of depression according to formal classification criteria that includes both inclusion and exclusion components, the standard practice in research investigations has been the use of diagnostic clinical interviews. Structured clinical interviews are typically formulated to evaluate all symptoms, their duration, and potential exclusion criteria as specified by a formal set of diagnostic criteria. In this manner, the K-SADS (Puig-Antich & Chambers, 1978) was designed to provide diagnostic information on disorders in youngsters according to the RDC (Spitzer et al., 1978). Likewise, *DSM* criteria for psychiatric disorders are assessed by other interviews such as the Child Assessment Schedule (Hodges, Kline, Stern, Cytryn, & McKnew, 1982), Diagnostic Interview for Children and Adolescents-Revised (Reich & Welner, 1988), and the Diagnostic Interview Schedule for Children-Revised (Shaffer et al., 1993); see Hodges' (1994) and Reynolds' (1992b) reviews of these and other clinical interview measures.

Self-report severity measures typically evaluate a range of depressive symptoms with the assessment format specific to the depth of symptom expression (e.g., frequency of occurrence, severity, etc.). Most of these measures generally provide a total score that may be compared to a derived cutoff score. In this manner, many severity measures of depression allow for the evaluation of a clinical level of depressive symptomatology, assuming an adequate coverage of the symptom domain (Reynolds, 1994). Using the nomenclature of Compas, Ey, and Grant (1993), single-scale self-report depression measures assess depressed mood in youngsters, and self-report measures that are components of a comprehensive assessment measure or that were developed to assess all symptoms of classification system specified depressive disorders allow for the assessment of depressive syndromes. Thus, self-report scales are not designed as diagnostic measures.

Limitations on the use of self-report are primarily developmental. Linguistic competence, including reading and comprehension ability, are important considerations when using self-report measures. These task demands suggest that most youngsters aged eight years and above who do not have learning problems can respond to self-report measures that include language at a third-grade reading level. To avoid confounding with reading, it is recommended that measures be read to youngsters below 10 years of age. Likewise, it is important to consider metacognitive demands of the measure. Thus, task demands go beyond reading to include the ability to recognize one's emotional and behavioral characteristics as they apply to a specified time-frame and evaluate the frequency, severity, or nature of these characteristics.

The ability of the youngster to self-monitor their behavior and emotions as well as self-evaluate these facets is a requirement of most measures. There are a number of additional developmental aspects specific to assessment of depression in children that are of primary concern to the assessment of young children rather than adolescents and address both the reliability and validity of measures of depression in youngsters. Many of these issues are generic to the use of self-report methods with children and are described in more detail elsewhere (Reynolds, 1992b).

As a function of the limitations noted above, there are few self-report measures that can be used with children below the age of eight years, although there is some research to suggest that self-report measures of depression can be used with children as young as ages 5 or 6 years. (Ialongo, Edelsohn, Werthamer-Larsson, Crockett, & Kellam, 1993). For children aged six and above, clinical interviews, such as the Children's Depression Rating Scale-Revised (CDRS-R; Poznanski et al. 1984) may be used, although some youngster's metacognitive ability for emotions may limit their response. Thus, for young children, parent reports using clinical interviews are a primary source of information, with parent's reports also of value for school-age children, assuming reliable and valid reporting on the part of the parent.

5.17.4.1 Self-report Measures of Depression for Children and Adolescents

Since the mid-1970s, a number of self-report measures have been developed for the assessment of depression in children and adolescents, with some researchers and clinicians using measures designed for use with adults. The use of self-report questionnaires for the assessment of depressive symptomatology in young people has witnessed a rapid growth in research and clinical applications. From a few reports in the early 1980s, to the routine use of self-report depression measures in a wide range of child and adolescent mental health disciplines, self-report measures provide a simple and direct method for the evaluation of the clinical severity of depressive symptoms in children and adolescents. Table 2 lists the more common self-report measures used in North America. These measures are among the most frequently used self-report scales for the assessment of depressive symptomatology in children and adolescents (Archer, Maruish, Imhof, & Piotrowski, 1991). A brief description of several of these measures is provided below. More information on these and other self-report measures of depression in children and adolescent is given by Reynolds (1994).

5.17.4.1.1 Children's Depression Inventory

The Children's Depression Inventory (CDI; Kovacs, 1979, 1992) as described by Kovacs and Beck 1977) was originally developed as a downward revision of the Beck Depression Inventory (BDI; Beck, Ward, Mendelson, Mock, & Erbaugh, 1961). The CDI is one of the most frequently used research measures of depression in children and consists of 27 items, each evaluating a symptom of depression or related affect. Items are presented as three statements of varying symptom severity. Several of the items may be confusing to some children (e.g., I do not do what I am told most of the time).

The CDI manual (Kovacs, 1992) presents normative data based on a sample of 1266 children and young adolescents from an unspecified number of schools in Florida. Data appear to be a subsample of youngsters from a previously published study by Finch, Saylor, and Edwards (1985). Data on the race or ethnicity of the standardization sample is not

Table 2 Description of self-report measures of depression used with children and adolescents in North America.

Measure/authors	*Development target population*	*Number of items*	*Response format*	*Manual available*
Children's Depression Inventory Kovacs (1979, 1992)	children/adolescents	27	3-alternative	Yes
Children's Depression Scale Lang and Tisher (1987)	children/adolescents	66	card sort	Yes
Reynolds Child Depression Scale Reynolds (1989)	children	30	Likert 4-point	Yes
Reynolds Adolescent Depression Scale Reynolds (1986b)	adolescents	30	Likert 4-point	Yes
Beck Depression Inventory Beck, Ward, Mendelsohn, Mock, and Erbaugh (1961)	adults	21	4-alternative	Yes[a]

[a] The manual for the Beck depression inventory is specific to the use and characteristics of the BDI with adults.

reported, and data is provided for children in grades 2 through 8. Norms are not provided for high school students. Although not indicated in the manual, the normative sample data was based on an oral administration of the CDI as indicated in the original article by Finch et al. (1985). The CDI manual has been reviewed by Reynolds (1994).

The psychometric characteristics of the CDI have been reported in many studies. Researchers typically report internal consistency reliability coefficients in the low to upper 0.80s (Cole & Carpentieri, 1990; Kovacs, 1983; Reynolds, Anderson, & Bartell, 1985; Smucker, Craighead, Craighead, and Green, 1986) and test–retest reliability coefficients ranging from 0.38 to 0.87 (Finch, Saylor, Edwards, & McIntosh, 1987; Kovacs, 1980/1981, 1983; Nelson & Politano, 1990; Saylor, Finch, Spirito, & Bennett, 1984; Smucker et. al., 1986; Weiss et al., 1991). The variability in test–retest reliability is in part a function of the time interval between assessments and the sample characteristics.

One line of research has examined the utility of the CDI in distinguishing between depressed and nondepressed youngsters (e.g., Curry & Craighead, 1990; Fristad, Weller, Weller, Teare, & Preskorn, 1988; Moretti, Fine, Haley, & Marriage, 1985; Saylor et al., 1984). The results of these studies are mixed and tend to show a lack of diagnostic efficacy.

Although not designed as a diagnostic measure the CDI is useful in assessing the severity of depressive symptomatology. One question that has emerged is whether a particular cutoff score can represent a clinically relevant level of depressive symptoms on the CDI. A cutoff score of between 17 and 19 appears to be appropriate, given the score distributions for the CDI found with various school-based and clinical samples of children. In samples of school-based or nondepressed youngsters a mean CDI score of 8–10, and a standard deviation of 7–8 points is typically reported (Cole, 1991; Cole & Carpentieri, 1990; Craighead, Curry, & Ilardi, 1995; Finch et al., 1985; Ollendick, Yule, & Ollier, 1991; Smucker et al., 1986; Saylor et al., 1984). In large samples of nonreferred children a score of 19 identifies approximately 10% of the sample.

5.17.4.1.2 Reynolds Child Depression Scale

The Reynolds Child Depression Scale (RCDS; Reynolds, 1989) is a 30-item self-report measure designed for use with children aged 8–13. On the RCDS 29 items are rated as to the frequency of their occurrence during the past two weeks using a four-point "almost never" to "all the time" response format. Items are worded to evaluate current symptom status (e.g., item 8: I feel like crying; item 14: I feel like hurting myself). Seven items are reverse keyed (e.g., item 25: I feel like having fun) with a negative response indicative of depressive symptom status. Item 30 consists of five smiley-type faces ranging from sad to happy, that the child completes by placing an X over the face that indicates how he or she feels and represents an evaluation of dysphoric mood.

The RCDS has been used in a number of descriptive and intervention studies of depression in children (e.g., Bartell & Reynolds, 1986; Huebner, Scott, & Alderman, 1993; Rawson, 1992; Reynolds et al., 1985; Reynolds & Graves, 1989; Roseby & Deutsch, 1985; Smoller & Brosgole, 1993). The manual for the RCDS provides normative information on over 1600 children representing heterogeneous ethnic and socioeconomic backgrounds, along with procedures for administration, scoring and interpretation, and data on reliability and validity. The internal consistency reliability of the RCDS with the standardization sample was 0.90. Internal consistency reliability of the RCDS with samples of normal and depressed youngsters have ranged from 0.87 to 0.92 (Bartell & Reynolds, 1986; Crowley & Emerson, 1996; Reynolds, 1989; Reynolds et al., 1985; Reynolds & Graves, 1989). Reynolds and Graves (1989) report a test–retest reliability coefficient of 0.85 for the RCDS using a four-week interval between testing with an ethnically diverse sample of 220 children from grades 3 through 6, and a mean difference in RCDS scores between the two assessments of less than two points.

Validity data for the RCDS have been reported in the form of high correlations with other self-report and clinical interview measures of childhood depression, as well as content validity, factor analysis, discriminant validity, and clinical utility (Reynolds, 1989). Researchers have reported correlations between the RCDS and the CDI ranging from 0.70 to 0.79 across several studies (e.g., Bartell & Reynolds, 1986; Crowley & Emerson, 1996; Reynolds, 1989; Reynolds et al., 1985). Reynolds (1989) reports a correlation between the RCDS and CDRS-R of 0.76. Using the CDRS-R cutoff score to provide a base rate for a clinical level of depression, Reynolds (1989) reported a specificity rate of 97%, sensitivity of 73%, a Yule's Y of 0.81 ($P < 0.0001$) and a phi coefficient of 0.73 ($P < 0.0001$) for the RCDS cutoff score with a sample of 82 children. A number of studies (e.g., Rawson & Tabb, 1993; Stark, Reynolds, & Kaslow, 1987) have shown the RCDS to be sensitive to treatment outcome as a measure of depression.

5.17.4.1.3 Children's Depression Scale

The Children's Depression Scale (CDS; Tisher & Lang, 1983) was developed in Australia and uses a modified card-sort response format with its 66 items individually listed on cards and the child sorting the cards into one of five boxes labeled: very wrong, wrong, don't know/not sure, right, and very right. The CDS evaluates two broad factors, with 18 items comprising a "positive affective experience" (P score) subscale, and the remaining 48 items a depression subscale (D score). The positive affect scale includes one subscale of eight items (pleasure and enjoyment), with the remaining items on the P scale described as miscellaneous (Lang & Tisher, 1987). The depression subscale includes five subscales, (affective response, social problems, self-esteem, sickness and death, guilt, and pleasure and enjoyment) along with nine additional miscellaneous items. A manual by Lang and Tisher (1987) for use in North America was published with norms based on 37 normal children from Australia. There is also an adult-respondent form of the CDS (Tisher, 1995).

Several studies have described the psychometric characteristics of the CDS. Tisher, Lang-Takac, and Lang (1992) report on a test–retest study by Tonkin and Hudson (1981) who found a one week test–retest reliability coefficient of 0.74 for the CDS with a sample of 60 children. Internal consistency reliability has been found to be high, ranging from 0.92 to 0.94 (e.g., Bath & Middleton, 1985; Kazdin, 1987). Kazdin (1987) with a clinical sample of 185 children, reported correlations of 0.48 and 0.51 between child report on the CDS D scale and scores on the CDI and a modified form of the BID interview, respectively.

The CDS appears to be a reliable child self-report measure, although the number of items and format make administration and scoring a bit cumbersome. The lack of sufficient normative data is a limitation for the clinical use of this measure.

5.17.4.1.4 Reynolds Adolescent Depression Scale

The Reynolds Adolescent Depression Scale (RADS; Reynolds, 1986b) is designed to evaluate the severity of depressive symptoms in adolescents aged 12–18. The RADS consists of 30 items written to reflect symptoms delineated by the *DSM-III* (APA, 1980) for major depression and dysthymic disorder, as well as additional symptoms delineated by the RDC. Items on the RADS require a third-grade reading level. Although written at the time *DSM-III* was in effect, there have been few changes in symptoms and criteria for depressive disorders between *DSM-III*, *DSM-III-R* (APA, 1987), and *DSM-IV* (APA, 1994). Items on the RADS evaluate a range of symptom domains, including somatic, motivational, cognitive, mood, and vegetative components of depression.

The RADS was normed on an ethnically diverse sample of 2460 adolescents ages 12–19 years. The RADS norms appear to be relatively robust, with similar mean scores reported in a number of other studies of school-based youngsters in the USA and Canada (Dalley, Bolocofsky, Alcorn, & Baker, 1992; Reynolds & Miller, 1989; Schonert-Reichl, 1994; Weist, Proescher, Freedman, Paskewitz, & Flaherty, 1995). The RADS has been used as a measure of depressive symptomatology in numerous studies with school-based and clinical samples of adolescents (Adams & Adams, 1993; Adams, Overholser, & Spirito, 1994; Brand, King, Olson, Ghaziuddin, & Naylor, 1996; King et al., 1996; King, Hovey et al., 1997; King, Radpour, Naylor, Segal, & Jouriles, 1995; King, Raskin, Gdowski, Butkus, & Opipari, 1990; King, Segal et al., 1995; King, Segal, Naylor, & Evans, 1993; Licitra-Kleckler & Waas, 1993; Nieminen & Matson, 1989; Sadowski & Kelley, 1993; Wurzbacher, Evans, & Moore, 1991).

The reliability of the RADS is generally reported as high, ranging from 0.91 to 0.96 with samples of normal and depressed adolescents ranging in size from 62 to 2120 (Dalley et al., 1992; Reynolds, 1987, 1990; Reynolds & Coats, 1982; Reynolds & Miller, 1989; Schonert-Reichl, 1994). Test–retest reliability based on a sample of 104 adolescents who were tested with a six week interval between testings was 0.80. A 12 week test–retest reliability coefficient of 0.79 was also found for the RADS with a sample of 415 high school students (Reynolds, 1987). More recently, Reynolds and Mazza (in press) reported a test–retest reliability coefficient of 0.87 in a sample of 89 young adolescents from an inner-city school with an average retest interval of three weeks.

The validity of the RADS has been shown in relationships with other depression scales and measures of related constructs. The RADS has demonstrated strong correlations with other self-report measures of depression, including the BDI (Beck et al., 1961), and Center for Epidemiological Studies depression scale (Radloff, 1977) (r = 0.71–0.89). Kahn, Kehle, and Jenson (1987) in a study of 349 adolescents found a correlation of 0.75 between the RADS and CDI. Shain, Naylor, and Alessi (1990) in a sample of 45 adolescent inpatients with major depression, reported a correlation coefficient of 0.87 between the RADS and CDI.

Criterion-related validity of the RADS has been shown using semistructured clinical interviews of depression. In a study of 111 adolescents, Reynolds (1987) reported a correlation of 0.83 between the RADS and the Hamilton Depression Rating Scale (HDRS; Hamilton, 1967). In their study of adolescents with major depression, Shain et al. (1990) reported a correlation of 0.73 between the RADS and the HDRS. Reynolds and Mazza (in press) found a correlation of 0.76 between the RADS and HDRS. Overall, in studies of clinical samples of adolescents, investigators have reported strong evidence for criterion-related validity for the RADS with diagnostic and semistructured clinical interview measures of depression (King, Katz et al., 1997; Reinecke & Schultz, 1995).

The RADS uses a cutoff score to describe a clinical level of depressive symptom severity. The RADS cutoff score has been validated in several studies, using both HDRS scores as well as formal diagnosis based on the SADS as criterion measures (Reynolds, 1987). Using the RADS cutoff score of 77 and a HDRS cutoff of 15 with a subsample of 32 adolescents from a psychiatric center, Carey, Kelley, and Carey (1991) reported that 78.1% were correctly classified using the cutoff scores on these two measures.

In a study of adolescents with major depression and an age and sex matched normal control group, Shain et al. (1991) found significant differences in RADS scores between youngsters with major depression (M = 85.5) and normal controls (M = 45.5) t = 9.02, $p < 0.0001$. Reynolds and Mazza (in press) reported a hit rate of 94% and a kappa coefficient of 0.71 using the RADS cutoff score in comparison to a clinical cutoff score of 16 on the HDRS. The RADS has demonstrated clinical efficacy in its use in a number of adolescent depression treatment studies (Hains, 1992; Kahn, Kehle, Jenson, & Clark, 1990; Reynolds & Coats, 1986).

5.17.4.1.5 Beck Depression Inventory

The BDI (Beck et al., 1961) was developed for adults and consists of 21 items, each consisting of four statements of varying degrees of symptom severity. A number of investigators have used the BDI with adolescents, although the reading requirements and format of the scale present difficulty for some youngsters. Users of the BDI often apply cutoff scores used with adults to adolescents without adequate validation.

Internal consistency reliability of the BDI with adolescents has been reported in the 0.70s to 0.80s (Kashani, Sherman, Parker, & Reid, 1990; Reynolds & Coats, 1982; Roberts, Lewinsohn, & Seeley, 1991; Strober, Green, & Carlson, 1981). Strober et al. (1981) reported a five-day test–retest reliability of 0.69 in a sample of 78 psychiatric inpatient adolescents, similar to the short-term test–retest reliability of 0.67 reported by Roberts et al. (1991) with a large sample of school-based youngsters. In a study of 37 older adolescents, Kutcher & Marton (1989) found a one-week test–retest reliability coefficient of 0.83. Overall, the reliability of the BDI with adolescents is lower than that found in other self-report measures of depression developed specifically for youngsters.

Validity evidence for the BDI has been mixed in clinical and school-based samples. Barrera and Garrison-Jones (1988) with a sample of hospitalized psychiatric patients (*n* = 65) and school-based adolescents (*n* = 49) reported reasonable sensitivity and specificity in the school sample but poor results for the psychiatric sample. Kashani et al. (1990) noted a relatively low sensitivity rate (48%) using the BDI cutoff score of 16 in a sample of 100 clinic referred adolescents. Roberts et al. (1991) in a study of 1704 adolescents who completed the BDI as well as a diagnostic interview, found a correlation of 0.50 between the BDI and a 14-item form of the HDRS, which is relatively low, with low kappa coefficients for the BDI in identifying cases of major depression ($\kappa = 0.14$) and dysthymia ($\kappa = 0.03$). The somewhat lower reliability, adult language and comprehension demands, and issues of validity of the BDI cutoff score with adolescents are issues that should be recognized in the use of the BDI with adolescents.

5.17.4.2 Clinical Interview Severity Measures of Depression

A number of diagnostic and severity interview measures have been developed for the evaluation of depression in children and adolescents. As noted earlier, diagnostic measures that assess the wide range of psychopathology found in young people will not be discussed in this chapter. Described below are two semistructured clinical interviews that evaluate the severity of depressive symptoms, in youngsters. These measures, the CDRS-R (Poznanski et al., 1984) and the HDRS (Hamilton, 1967) have been used in research and treatment outcome applications.

5.17.4.2.1 Children's Depression Rating Scale-Revised

The CDRS-R (Poznanski et al. 1984) was originally developed in 1979 (Poznanski et al., 1979) and is a semistructured clinical interview measure of the severity of symptoms of depression designed for use with children aged 6–12. The CDRS-R consists of 17 items, each representing a depressive symptom, and rated on a 1 (normal) to 7 (severe) scale. On the CDRS-R, 14 of the items are presented in an interview format, and three items (depressed affect, tempo of language, and hypoactivity) are observational. The CDRS-R requires 20–30 minutes to administer.

Poznanski and her colleagues (Poznanski et al., 1979; Poznanski, Cook, Carroll, & Corzo, 1983; Poznanski, Carroll, Banegas, Cook, & Grossman, 1982) have reported acceptable levels of reliability and evidence of validity of the CDRS in differentiating RDC-diagnosed youngsters. Poznanski, Freeman, & Mokros (1985) recommends a score of 40 and above on the CDRS-R as a clinical cutoff for depression in children. Using a cutoff score of 44, Jensen, Burke, and Garfinkel (1988) reported sensitivity of 50% and specificity of 79% for a diagnosis of major depression in a sample of 35 youngsters aged 8–18, 12 of whom had a diagnosis of major depression. Heiligenstein and Jabobsen (1988) modified the CDRS-R with the removal of somatic items for the evaluation of depression in medically ill youngsters. The CDRS and CDRS-R have been used as severity measures in research on depression in children and adolescents (e.g., Mokros, Poznanski, Grossman, & Freeman, 1987; Shain et al., 1990; Weller, Weller, Fristad, Cantwell, & Preskorn, 1986), and the CDRS-R was used as an outcome measure in treatment studies of depression in children by Liddle and Spence (1990) and Stark et al. (1987).

5.17.4.2.2 Hamilton Depression Rating Scale

The HDRS (Hamilton, 1960, 1967) is a clinical interview measure of the severity of depressive symptoms and one of the most frequently used outcome measures in psychiatric studies of depression in adults. There are several versions of the HDRS, the most popular being the 17 item form. Items are evaluated by the clinician as to their severity with higher scores indicative of greater depressive pathology. Two items that assess psychomotor retardation and psychomotor agitation, are observational. Items on the HDRS are scored from 0 to 4 or 0 to 2 depending on the symptom assessed, with high scores indicating greater symptom pathology. Researchers have utilized a number of cutoff scores to delineate a clinical level of depressive symptomatology, with such scores typically ranging from 15 to 20.

There are a number of caveats to the use of the HDRS. It should be noted that a number of contemporary symptoms of depression are not evident on the HDRS (e.g., low self-esteem, self-deprecation, etc.). Likewise, several items dealing with loss of insight, hypocondriasis, and several anxiety items are tangentially related to depression. Nevertheless, as a severity measure of depression, the HDRS, with minor adjustments for age differences, works quite well with adolescents.

Research using the HDRS has included both clinical and nonclinical samples of adolescents

(Alessi, McManus, Grapentine, & Brickman, 1984; King, Naylor, Hill, Shain, & Greden, 1993; King, Segal et al., 1995; King et al., 1996; Reynolds, 1987; Shain et al., 1990). Reynolds (1987) found an internal consistency reliability of 0.91 for the HDRS with a sample of 111 school-based adolescents, and Reynolds and Mazza (in press) reported a reliability of 0.85 with young adolescents. Robbins, Alessi, Colfer, and Yanchyshyn (1985) obtained an interrater reliability of 0.90 with a sample of adolescent psychiatric inpatients. King, Naylor, Segal, Evans, & Shain (1993) reported an interrater reliability of 0.97 in a sample of 30 depressed and nondepressed adolescents.

5.17.4.3 Assessment Summary

A number of interviews and rating scales developed for the assessment of depression in children and adolescents have been described. A positive outcome since the mid-1980s in the study of depression in children and adolescents has been the development of diverse methodologies and procedures for the assessment of this disorder in youngsters. Although the role of child self-report in the evaluation process has been stressed, the availability of other rich sources of information can only serve to increase our perspectives regarding the mental health of children and adolescents. An examination of measures for the evaluation of depression in youngsters indicates that there is no one right or correct measure. Rather, there are different measures designed for different assessment purposes. Furthermore, the variance in sources of information about a youngster's depression, although disconcerting to researchers and scientists who often seek parsimony among measures of the same construct, may suggest that there is also no one right or correct source of information. The issue of differences in reports among sources of information, or informant variability is a complex issue that has developmental as well as psychometric underpinnings. Additional information on this issue as it relates to the assessment of depression in children and adolescents is given by Kazdin (1994).

It is recommended that the evaluation of depression in a child, particularly a young child, involves multiple assessment measures and, where possible, multiple assessment methods (e.g., self-report, clinical interview, reports by significant others). Waller and Rush (1983) have provided an interesting approach to assessment and diagnosis of depression in children which incorporates formal psychological assessment, medical procedures, and response to treatment for distinguishing primary depression, organic affective syndrome, and situational depression in children. As found in numerous research studies, disagreements occur across methods and measures. In such cases, a close examination of the specific assessment information is warranted, with the clinician deciding how best to combine these data. In the above discussion of depression assessment measures, there is an evident gap in procedures for the evaluation of depression in children below the age of 6 or 7 years.

5.17.5 PSYCHOLOGICAL TREATMENT OF DEPRESSION IN CHILDREN AND ADOLESCENTS

It is evident that depression is a serious psychological disturbance that is experienced by a very large number of children and adolescents. Surveys and studies of service utilization suggest that most of these youngsters do not receive treatment of any type (Keller et al., 1991). The high prevalence rate combined with the potential range of long-term negative consequences (e.g., Kovacs, 1996b) supports the need and requirement for effective treatment procedures. Treatment approaches for depression in children and adolescents are, for the most part, modifications or direct applications of procedures developed for use with adults. Depressed youngsters represent a particularly vulnerable population. Unlike children and adolescents with externalizing problems, such as conduct disorder, for whom treatment may be viewed by the youngster as undesirable or even punitive, depressed youngsters often see treatment as a potential avenue to reduce or alleviate their severe distress.

The empirical evidence for the efficacy of contemporary psychological treatments for depression in children and adolescents is limited to fewer than a dozen studies that have been conducted since 1980. Thus, for practical purposes, our evidence for the use of contemporary psychotherapies for the treatment of depression in youngsters is predicated on the results of these investigations. The use of psychoanalytically based treatments has a somewhat longer history, although there is limited empirical evidence to support therapeutic efficacy.

5.17.5.1 Range of Therapeutic Approaches

There are a multitude of treatment modalities across the two primary domains of psychological and somatic approaches. The latter include the use of antidepressant medications, such as tricyclics, monoamine oxidase inhibitors, specific serotonin reuptake inhibitors, and lithium carbonate. These procedures have generated a body of empirical research that allows for the evaluation of their clinical efficacy although, as in the case with psychotherapy, the number of studies is small in comparison to research with adults.

As noted, there have been fewer than a dozen empirical demonstrations of the efficacy of psychological treatments designed for the amelioration of affective disorders and depressive symptoms in children and adolescents. The small number of experimental studies on the psychological treatment of depression in children and adolescents is perplexing, particularly given the large number of empirical outcome studies on the treatment of depression in adults. However, a similar situation exists with regard to the number of pharmacological interventions for depression in young people in comparison to the large number of studies of antidepressant efficacy with adults.

A brief overview of control-group studies of psychotherapy for the treatment of depression in children and adolescents is presented in this chapter. Case reports, including single-subject designs, have been reported and been reviewed previously (Reynolds, 1992b).

5.17.5.2 Control-group Investigations

For the demonstration of clinical efficacy and generalizability, control-group experimental treatment studies that provide data on the efficacy of psychological treatments for depression in children and adolescents are of significance. The majority of the published empirical, control group investigations have utilized a range of cognitive-behavioral procedures, and have typically compared youngsters receiving such treatment with groups of youngster who receive another potentially active treatment, therapeutic support, and/or are assigned to a wait-list condition and do not receive treatment during the period of study. A number of contemporary psychotherapy investigations for depression in children and adolescents are briefly described below and summarized in Tables 3 and 4. In the majority of controlled group investigations reported below, structured therapy manuals have been developed that provide evidence for the combination of specific treatment components.

In addition to studies reported in peer-reviewed publications, a number of investigators have provided partial descriptions of treatment outcome studies within books or chapters in books. Results of a cognitive-behavioral intervention for depression with children were described in Stark (1990) and in a chapter by Stark, Rouse, and Livingston (1991) who reported on treatment outcome with 24 children who were randomly assigned to a cognitive-behavioral (self-control, social skills, relaxation training, and cognitive restructuring) or traditional counseling intervention (therapeutic discussion and support). Family therapy, consistent with treatment components of each condition was also provided. Treatments consists of 24–26 sessions of 45–50 minutes over a $3^1/_2$ month period administered in small groups of four youngsters to a group. Both conditions showed significant decreases in depressive symptomatology in participants at posttreatment with treatment gains maintained at a seven month follow-up. On one outcome measure, the cognitive-behavioral group was superior to the counseling condition, although this difference was not found at follow-up. Actual test score means for the groups at various assessment points were not provided by the authors.

5.17.5.3 Psychotherapy Treatment Studies with Children

One of the first control group treatment studies for depression in children was reported by Butler, Miezitis, Friedman, and Cole (1980) who compared a role play condition that emphasized role play, social skills and social problem solving and a cognitive restructuring treatment based in part on rational-emotive therapy. Control groups consisted of an attention and waitlist condition. Participants were a school-based sample of 54 moderately depressed fifth and sixth grade children. The active treatments and attention condition consisted of 10 one-hour sessions conducted in small groups of six or seven children. A pretest–post-test design was used, although the authors did not conduct a follow-up evaluation to determine the maintenance of treatment gains. Multiple outcome measures were used, with the CDI the only measure of depression. At the post-test, significant decreases in CDI scores were found for the two active treatment conditions, as well as for the waitlist control group. The attention group remained relatively unchanged in their self-reported level of depressive symptomatology.

The results of the Butler et al. (1980) investigation were somewhat mixed. Although decreases were found for the two active treatments, the level of mean CDI scores for these groups at post-test (14 and 16 points) may be considered elevated. Likewise, the decrease in scores seen in the waitlist, but not the attention placebo control is puzzling. A significant methodological problem was the failure to include a follow-up assessment in the research design. In this sense, the extent to

Table 3 Summary of controlled group psychological interventions for depression in children and adolescents.

which the groups maintained treatment gains and evaluation of treatment generalization is unknown. This study is noteworthy in that it appears to be the first published experimental group intervention for depression in children, and it used an attention control condition.

Stark et al. (1987) compared a cognitive-behavioral treatment that was largely predicated on self-control and attribution retraining components, and a behavioral problem-solving treatment that utilized components of interpersonal problem-solving, increased engagement in pleasant activities, and self-monitoring to a waiting list control condition. Participants at post-testing were 28 moderately depressed children, aged 9–12. Assessment measures included the RCDS, CDI, and CDRS-R along with measures of related domains. The intervention was school-based and consisted of 12 50-minute sessions administered in small groups over a five-week period.

At post-testing, both active treatments demonstrated significant improvement in depressive symptomatology while the difference for the waiting list control group was nonsignificant. An eight-week follow-up showed a general maintenance of the treatment effects, with some children in the self-control condition showing continued improvement from post-test to follow-up. Children in the waiting list condition were treated after the post-test and were not included in the between-group comparisons at follow-up. Results indicated that the treatments were reasonably effective, with 88% of the children in the self-control group and 67% of those in the behavioral group reporting nondepressed levels of depressive symptomatology at the follow-up assessment. On the basis of this study and further development of active components, Stark (1990) has provided a more comprehensive treatment program for depression in children that is expanded in its scope, content, and duration.

In a study conducted in Australia, Liddle and Spence (1990) compared social competence training (SCT) intervention that included cognitive and behavioral treatment components, to an attention placebo control group, and a waiting list control group with a sample of 31 children aged 7–11. The authors indicated that children were identified based on a multiple-source multiple-stage screening procedure recommended by Reynolds et al. (1985). Children were selected from the population of regular class youngsters attending two Catholic schools in Sydney, Australia, and for whom parental permission for assessment was provided. Children were administered the CDI, which was read to younger-age children and those with reading problems. A cutoff score of 19 was used to select children for the second stage of the assessment procedure. Of the 380 children tested, 70 (18.4%) obtained a score of 19 or higher on the CDI. Two weeks following the initial screening, the CDRS-R was individually administered to the 70 youngsters. Using a cutoff score of 40 on the CDRS-R, 33 children were identified as demonstrating a clinical level of depression.

Of the 33 children identified, permission from parents for child participation in treatment was obtained for 31 youngsters. It is interesting to note that there were 10 girls and 21 boys, suggesting a gender difference of 2 to 1, with boys demonstrating a higher rate of depression, assuming that there was minimal difference in the proportion of males and females in the total sample. The mean age of the sample was 9.2 years (SD = 1.15). For the total treatment sample the mean CDI score was 21.32, with a mean of 42.03 on the CDRS-R, suggesting a moderate to severely depressed sample. Participants were randomly assigned to either a SCT condition ($n = 11$), an attention placebo control (APC) ($n = 10$), or a waiting list control group ($n = 10$).

Treatment for the SCT and APC consisted of eight one-hour sessions administered once a week to youngsters in groups of 4–6 children. The waiting list group did not receive any treatment and were evaluated at pretest, post-test, and at a three month follow-up evaluation. The SCT intervention focused on teaching social skills, interpersonal problem solving, and included components of cognitive restructuring. Self-monitoring of negative thoughts was also included. There appear to be similarities between treatment components of the SCT program and the behavioral problem-solving intervention developed by Stark et al. (1987). The attention/placebo control consisted of teaching drama to participants and appears to be more of an attention control condition rather than a placebo treatment.

At post-testing, all groups showed a modest decrease in CDI scores with no difference in treatment efficacy between groups. Unfortunately the CDI was the only depression measure used to evaluate treatment effects. Similar findings were reported for the follow-up assessment. Overall, the SCT intervention failed to produce meaningful treatment effects beyond those found in the attention and waitlist control conditions. This is an interesting study that appears to be the first to include younger children (i.e., age seven years and above). The lack of clinical efficacy is somewhat unexpected given previous studies and may be in part a function of the younger age of participants.

5.17.5.4 Psychotherapy Treatment Studies with Adolescents

In the first published control group treatment study for depression in adolescents, Reynolds and Coats (1986) compared a cognitive-behavioral treatment, a relaxation training group, and a waiting list control group with a sample of 30 moderately to severely depressed high school students. The two active treatment conditions were administered in 10 50-minute sessions twice a week for a five-week period. A follow-up assessment was conducted after four weeks from the end of treatment. Assessment measures included the RADS, BDI, and BID, along with measures of related constructs (e.g., anxiety, self-esteem). A school-based screening procedure was used to identify participants with the pretest representing a second assessment point. Both active therapies were presented in a structured format, with detailed treatment manuals established for each condition. The cognitive-behavioral therapy used procedures found in similar treatments of depression in adults, with modifications made for developmental and situational (e.g., home, school, peer-group, etc.) differences of adolescents. Components included teaching self-control procedures (i.e., self-monitoring, self-evaluation, and self-reinforcement), cognitive restructuring consistent with aspects of Beck's (1967, 1976) cognitive therapy, and procedures for increasing involvement in pleasant activities (Lewinsohn, Munoz, Youngren, & Zeiss, 1978). The relaxation training condition involved training in progressive relaxation procedures, along with guided imagery procedures. Both treatments were matched for therapist time and amount of homework assignments.

At post-testing, significant treatment gains for both active treatment conditions were found and maintained at the four week follow-up evaluation. Significant decreases in depression were reported by youngsters in the cognitive-behavioral and relaxation groups at post-test, with minimal change in the waiting list youngsters. Therapeutic effects of the interventions on participants' self-concept and level of anxiety were also reported by Reynolds and Coats (1986), with the relaxation training condition demonstrating the greatest reduction in self-reported anxiety.

Several of the treatment conditions of the Reynolds and Coats (1986) study were replicated by Kahn, Kehle, Jenson, and Clark (1990) who reported a treatment outcome study with 68 moderately depressed young adolescents. Treatment conditions for depression included cognitive-behavioral, relaxation training, and a self-modeling, along with a waitlist control group. The cognitive-behavioral treatment included pleasant activity scheduling and other behavioral components consistent with the approach of Lewinsohn et al. (1978), along with cognitive restructuring, self-control, and social skills training. The relaxation training group was similar to that of Reynolds and Coats (1986). Cognitive-behavioral and relaxation treatments were group administered in 12 50-minute sessions. The self-modeling treatment was individual with each youngster developing a three-minute videotape of themselves modeling nondepressive behaviors (e.g., smiling, positive verbalizations, and appropriate eye contact). Outcome measures included the RADS, CDI, and BID.

The authors reported significant treatment gains for the three active therapy conditions at post-testing and at a four week follow-up. The greatest therapeutic gains at post-testing and follow-up were found for the cognitive-behavioral and relaxation training conditions. The results of this investigation are consistent with Reynolds and Coats (1986), and suggest treatment generalizability as well as the efficacy of these procedures with young adolescents.

Lewinsohn, Clarke, Hops, and Andrews (1990) reported on the downward extension of the coping with depression course (Lewinsohn et al., 1978), a multimodal psychoeducational intervention for unipolar depression (Clarke & Lewinsohn, 1989). The sample consisted of 59 adolescents who met *DSM-III* criteria for major depression or RDC criteria for current minor or intermittent depressive disorder. Treatment conditions included: cognitive-behavior therapy group administered to adolescents only and consisting of 14 two hour sessions over a seven week period; the same cognitive-behavioral treatment administered to another group of adolescents along with group-training for parents (seven two-hour sessions) of these adolescents; and a waitlist control group.

The cognitive-behavioral intervention utilized a social learning approach to the treatment of depression, and included: pleasant activities scheduling; social skills training; cognitive restructuring; relaxation training; and a component focusing on communication, negotiation, and conflict resolution skills. The parent training included discussion of the components and skills taught to the adolescents and training in negotiation, communication and conflict-resolution skills.

Treatment outcome was reported for post-treatment, and follow-up assessments at 1, 6, 12 and 24 months. The waitlist condition was only available at post-testing. At post-testing, both active treatments demonstrated significant change as compared to the waitlist group, but were not significantly different from each other in their treatment efficacy. Treatment gains were maintained with a trend toward further improvement at follow-up assessments. The lack of the waitlist group as a comparison condition following post-treatment limited the long-term generalization of follow-up results.

In one of the few experimental studies conducted in a psychiatric setting, Fine, Forth, Gilbert, and Haley (1991) compared a social skills training group with a therapeutic support group for the treatment of depression in a group of 66 adolescent outpatients with a *DSM-III-R* diagnosis of major depression or dysthymia. The social skills condition consisted of self-monitoring of self and other's feelings, assertiveness training, conversation skills, social problem solving and conflict resolution. The therapeutic support treatment was designed as a therapeutic and supportive milieu for discussing problems and enhancing self-concept and self-worth. Outcome data (CDI and others measures) were reported for 47 youngsters who completed eight or more of the 12 treatment sessions. Within-group (pretest to post-test) differences indicated significant improvement for both treatments on a 12 item symptom scale derived from the K-SADS, with only the therapeutic support group showing significant post-test change on the CDI. Between-group analyses indicated the therapeutic support condition was superior on the K-SADS, with no difference between groups on the CDI. At a nine month follow-up there were no differences between groups on the outcome measures.

The results of this study are mixed. The social skills group showed minimal change in self-reported depressive symptoms on the CDI (pretest $M = 20.3$, post-test $M = 18.4$). On the K-SADS change from clinical to nonclinical levels was found in 50% of the therapeutic support group and 40% of the social skills group. This study suggests that social skills training alone may have limited therapeutic benefits. The superiority of the therapeutic support group suggests the potential utility of more interpersonal problem-solving therapies with adolescents.

In a study of 25 adolescent boys, 15–16 years of age, seeking training in stress management, Hains (1992) examined, in comparison to a waitlist control group, the efficacy of: a cognitive-behavioral intervention for stress inoculation based on the work of Meichenbaum (1985); an anxiety management procedure predicated on the work of Suinn (1986) with a strong relaxation training component. Although the focus of the study was on anxiety and stress management, depressive symptomatology was also examined at pretest, post-test, and follow-up. Interventions incorporated both group (three sessions) and individual (six sessions) therapy, with an 11 week follow-up conducted for the two active treatment conditions. Because of the selection criteria, group means on the RADS of participants suggested mild levels of depressive symptomatology, below means reported in other investigations (e.g., Kahn et al., 1990; Reynolds & Coats, 1986). However, given the small number of studies reported in the literature, this investigation is of interest, although it may be viewed as treating a subclinical level of depression. At post-testing, significant treatment gains on the RADS were found for the two active conditions in comparison for the waitlist group, with treatment groups maintaining treatment gains at follow-up.

In a study conducted in Canada with francophone youngsters, a cognitive therapy for depression was compared to a waiting list control group in a study of 25 depressed adolescents conducted by Marcotte and Baron (1993). The authors used a cognitive treatment package based on the rational-emotive model of depression. The treatment was administered in 12 60-minute sessions over a six week period. Participants were ages 14–17 years and were identified by the three-stage school-based screening procedure suggested by Reynolds (1986a). Significant treatment gains were found on the BDI in the cognitive group in comparison to the waitlist condition at post-test and at eight week follow-up.

As noted earlier, there have been several open trial studies of psychotherapies for the treatment of depression in adolescents. Although not described in detail in this chapter they are noted and present promising evidence for treatment efficacy. These studies are listed in Table 4. The study by Mufson et al. (1994) was based on a modification of the interpersonal psychotherapy of Klerman and Weissman (Klerman & Weissman, 1982). The modification of this intervention for adolescents was originally described by Moreau, Mufson, Weissman, and Klerman (1991) and more fully in Mufson, Moreau, Weissman, and Klerman (1993). Significant posttreatment gains in depressive symptomatology scores were found on the BDI and the HDRS.

A noncontrol group treatment study using cognitive therapy for depression in adolescents was reported by Belsher et al. (1995) with 15 adolescents who met criteria for *DMS-III-R* major depression. The authors reported significant reduction in depressive symptomatology at post-testing and two follow-ups (10 and 20 weeks) on the BDI and a clinician rating form of the Inventory of Depressive Symptomatology (Rush et al., 1986). It is also noteworthy that, similar to Mufson et al. (1993), the authors and colleagues have presented a more detailed description of their cognitive therapy for depression in adolescents in a book (Wilkes, Belsher, Rush, & Frank, 1994).

In both of the open trials noted above, significant reductions in depressive symptomatology were reported. However, as has been found in controlled group investigations, it is not uncommon to find symptom reduction also to occur in waitlist or control conditions, such that the primary focus is the demonstration of greater clinical efficacy of the active condition in comparison to control conditions. The same design issues apply to the evaluation of pharmacotherapies.

A significant finding from the majority of studies was the relative treatment efficacy of cognitive-behavioral therapies for the treatment of depression, with promising results reported for interpersonal psychotherapy. It is also noteworthy that treatment effectiveness was reported across therapies based on between 10 and 15 sessions, with treatment gains maintained at follow-up for most studies. This suggests that brief, structured contemporary psychotherapies are potentially efficacious for the treatment of depression in children and adolescents. Given what is known regarding the clinical efficacy of pharmacotherapies, contemporary psychotherapies should be considered as a general first line of treatment unless clinical data shows strong support for antidepressant treatment. For example, in a descriptive study of melancholic and nonmelancholic subtype adolescent psychiatric inpatients with major depression who were "significantly incapacitated by their symptoms," Robbins, Alessi, and Colfer (1989, p. 100) found that 68% of youngsters with nonmelancholic major depression responded to an intensive six week, broad-based psychosocial treatment without the use of medication. Adolescent inpatients with melancholic type major depression showed minimal response to psychotherapy, although 26% of these youngsters did show significant improvement with psychotherapy alone.

Given the lack of significant side-effects and the slow, but growing literature to suggest efficacy, contemporary psychotherapies for depression in children and adolescents need to be integrated into the standard of practice for the treatment of affective disorders in young people. It is also useful to note that in a study of treatment acceptability for interventions for depression in children, Tarnowski, Simonian, Bekeny, and Park (1992) found that mothers view psychological interventions to be significantly more acceptable than pharmacological, with cognitive-behavioral and behavioral interventions found somewhat more acceptable than social skills interventions. At this point, it appears that there is sufficient evidence to support the use of cognitive-behavioral procedures for the treatment of depression by clinicians. Based on the evidence of studies cited above, it does not appear that interventions with social skills enhancement or training are particularly useful as a stand-alone treatment. Further empirical study of interpersonal psychotherapy and other procedures should be undertaken to provide clinicians with a range of tested psychotherapeutic treatment approaches. Lastly, the efficacy of relaxation training has been noted in several studies, with its inclusion as a component noted in others, suggests that this approach may be viable for treating depression in some youngsters.

5.17.6 PHARMACOTHERAPY FOR DEPRESSION IN CHILDREN AND ADOLESCENTS

The use of medications for the treatment of mood disorders in children and adolescents has a long history compared to the application of psychotherapy. An examination of the pharmacological literature suggests that most empirical investigations of antidepressant medications for the treatment of depression (as well as a host of other disorders such as obsessive compulsive disorder [OCD], enuresis, school phobia, anxiety problems, etc.) have been conducted with children, with few investigations that focus on the treatment of depressed adolescents.

It is important to recognize that the administration of antidepressant medications does not result in a cure of the depression. Antidepressant drugs will show therapeutic effects in some youngsters; however, typically the symptoms of depression will return if the treatment is discontinued during the course of the depressive illness (Johnston & Fruehling, 1994).

The research on the efficacy of antidepressants with children and adolescents is growing as newer drugs and classes of antidepressants are placed on the market. Rather than review each of the dozen or so controlled studies of antidepressant therapy with children and adolescents, this chapter provides a brief review of the general findings and some of the issues inherent in the use of pharmacological agents with children and adolescents. It should be noted that in addition to pharmacotherapy, reports of electroconvulsive therapy (Bertagnoli

& Borchard, 1990) and light/phototherapy for seasonal affective disorder (seasonal pattern) (Sonis, Yellin, Garfinkel, & Hoberman, 1987) with depressed youngsters have been published. Light therapy has also been suggested as an adjunct in the treatment of depressive symptoms in bipolar disorder in adolescents (Papatheodorou & Kutcher, 1995). This chapter does not review studies of pharmacotherapy for treatment of bipolar disorder in children and adolescents. For bipolar disorder, lithium is one of the more commonly used drugs along with carbamazepine. The treatment of bipolar disorder in youngsters as well as adults is a difficult undertaking and frequently involves the testing of various drugs, singly and in combination. Data from research and clinical studies suggest that pharmacological agents used with adults for the treatment of bipolar disorder work about as effectively with young people (Carlson, 1994).

5.17.6.1 Pharmacotherapy for Depression in Children and Adolescents

A large number of case reports and a limited number of experimental studies have been published examining the efficacy of tricyclic antidepressants (TCAs), monoamine oxidase inhibitors, selective serotonin reuptake inhibitors (SSRIs), and other drugs for the treatment of unipolar depression, and lithium carbonate and other compounds for the treatment of bipolar disorder in children and adolescents. Pharmacotherapy of depression in children and adolescents is somewhat controversial due to the limited treatment response over placebo reported in numerous double-blind clinical trials. Reviews of the pharmacological studies for depression in young people can be found in Alessi, Naylor, Ghaziuddin, and Zubieta (1994), Jensen, Ryan, and Prien (1992), and Johnston and Fruehling (1994).

Since the mid-1980s, a number of newer antidepressants have appeared on the market with demonstrated efficacy for adults. Of particular note have been the SSRIs including fluoxetine, fluvoxamine, sertraline, and paroxetine. There have been reports of fluoxetine use with youngsters (e.g., Dech & Budow, 1991; Naylor & Grossman, 1991), although at the time of this chapter the author could not find published controlled group outcome studies using these agents for depression in youngsters. Initial research with fluoxetine by Riddle, Hardin, King, Seahill, & Woolston (1990), with a sample of 10 youngsters with Tourette's syndrome and OCD, found mixed results specific to treatment of obsessive compulsive symptoms. Significant agitation was noted as a response to fluoxetine in four of the 10 participants, but there were minimal adverse biological side-effects. The latter may be expected, given the general lack of anticholinergic and antihistaminic side-effects with fluoxetine. Riddle et al. (1989) also reported a case of a fluoxetine overdose in an adolescent. Open trials of SSRIs have been reported by Apter et al. (1994), Boulos, Kutcher, Gardner, and Young (1992), and others. Initial reports suggest significant clinical efficacy for fluoxetine, even with youngsters who previous failed to respond to TCAs (Boulos et al., 1992).

By far, the majority of published, control group investigations of antidepressants for the treatment of depression in children and adolescents has utilized tricyclic antidepressants such as imipramine, amitriptyline, nortriptyline, and desipramine. Researcher reports on TCAs for the treatment of depression in children began to appear in the late 1960s and early 1970s (Frommer, 1967; Kuhn & Kuhn 1971; Ling et al., 1970; Weinberg et al., 1973). Stack (1971) reported on 490 depressed children, including 116 preschool children, treated with antidepressants, most of which were TCAs.

A general finding across controlled antidepressant treatment studies of depression in children and adolescents has been the lack of superiority of medications over placebo control conditions. Rationales for this lack of treatment efficacy have ranged from invalidity of the diagnosis of depression in children using current classification systems to errors in design methodology and insufficient sample size (Conners, 1992; Jensen et al., 1992). With regard to the latter, most of the published studies utilized relatively small sample treatment groups, such that power to detect a significant difference is often compromised. However, in a recent study by Kutcher et al. (1994) of desipramine for major depression in adolescents, 60 adolescents were studied after using a placebo washout phase prior to treatment. In this well-controlled investigation, antidepressant and placebo groups did not differ across a wide range of outcome measures including psychometric as well as laboratory assessments. A similar finding was reported by Kye et al. (1996) in a controlled study of amitriptyline for major depression in 31 adolescents (22 completers) with major depression, using a two-week placebo-washout period.

5.17.6.2 Summary of Pharmacological Interventions

The overriding conclusion from the majority of double-blind placebo-controlled studies is that the scientific data indicates antidepressants are not significantly more effective than placebo conditions in the treatment of unipolar depression in children and adolescents (Ambrosini, Bianchi, Rabinovich, & Elia, 1993; Elliot, 1992; Johnston & Fruehling, 1994). This has caused clinical and research dissonance, given the large number of youngsters who are treated with antidepressants by clinicians who report individual clinical efficacy (Fisher & Fisher, 1996). Johnston and Fruehling (1994) provided a comprehensive review of studies of antidepressant medications for the treatment of depression in children and adolescents up to that time. These authors note the overwhelming use of antidepressants in clinical practice and the lack of scientific evidence to support efficacy. With so many clinicians using these agents, Johnston and Fruehling (1994) suggest that clinicians may be seeing a level of clinical usefulness not evident in the drug studies. They also recommend that for most youngsters with depression “antidepressant medication should not be the ‘first-line’ treatment.” The dilemma of scientific evidence and clinical use of antidepressants has been debated (Eisenberg, 1996; Fisher & Fisher, 1996). It is evident that the jury is out as to whether antidepressants can be recommended for use with young people. This supports the need for further study of psychosocial interventions as well as the examination of the utility of combined pharmacotherapy–psychotherapy treatments for depressed young people. The evaluation of pharmacological treatments for depression in children and adolescents is complex, and the issue of side-effects, although not dealt with in this review, is significant and a major consideration in the use of antidepressant medication.

Lastly, as noted earlier, several case reports and an open trial have examined the combined efficacy of pharmacotherapy and psychotherapy. Given that psychotherapy is often seen as an important component of treatment along with antidepressant medications, there needs to be greater focus on the clinical outcome of combined pharmacotherapy and psychotherapy with depressed children and adolescents. The combinatory approach to treatment, that is, the use of both pharmacotherapy and psychotherapy, is consistent with the biopsychological perspective of childhood depression. The biopsychosocial approach suggested by Vasile et al. (1987) makes use of a consultation model for the recommendation of psychological, pharmacological, or combined therapies. This integrative and evaluative approach appears useful for the treatment of depressed children and adolescents.

5.17.7 COMORBIDITY OF DEPRESSION AND OTHER PSYCHOPATHOLOGY IN CHILDREN AND ADOLESCENTS

The study of the coexistence of other psychopathology along with depression in children, adolescents, and adults has emerged as a significant field of inquiry (Anderson & McGee, 1994; Caron & Rutter, 1991; Kendall & Clarkin, 1992). Comorbidity is a term originally used in medicine to describe the existence of a distinct, separate disease or disorder that is present during the course of a primary disorder or disease that is the focus of attention.

In the study of psychiatric disorders in children and adolescents, the finding of comorbidity is becoming increasingly evident. In a study of 476 new admissions by adolescents (mean age 15.6 years) to inpatient and outpatient settings in 29 clinical settings in 21 states, multiple diagnoses (two or more clinical disorders) at intake were found in 67% of the sample, with three or more concurrent disorders found in 26% of the sample (Reynolds, 1997b). Pfeffer and Plutchik (1989) in a study of comorbidity in children, found an average of 2.38 diagnoses in a sample of 106 inpatients and a mean of 2.35 diagnoses in a sample of 101 outpatients. The authors found 39 children with a primary diagnosis of major depression, only three (7.6%) of whom did not have a coexisting *DSM-III* Axis I or Axis II disorder. The most frequent comorbid disorder was dysthymic disorder (56.4%), followed by borderline personality disorder (46.2%), specific developmental disorder (38.5%), and conduct disorder (28.2%).

Alessi and Magen (1988), in a study of 160 child psychiatric inpatients, found that 48 (30%) children had three or more Axis I disorders. A higher rate of co-occurrence of three or more disorders was found among the 25 youngsters with a depressive disorder (52%) compared to the 135 children in the nondepressed psychiatric group (26%). The depressed youngsters included 16 children with major depression (MDD) and nine children with dysthymic disorder. Although the comorbidity of other Axis 1 and several Axis II disorders did not differ in proportion to that found in children with other diagnoses, there were some differences in comorbidity between youngsters with major depression and dysthymic disorder. Nearly 89% of dysthymic children also manifested an anxiety disorder, as compared to 25% of MDD children. The children with major depression also demonstrated a similar frequency of comorbidity with attention deficit disorder and conduct disorder. The high comorbidity between dysthymic disorder and anxiety disorders suggests that there may be some degree of nosological similarity between these forms of psychopathology.

The comorbidity with major depression was examined by Mitchell, McCauley, Burke, and Moss (1988) separately for children ($n = 45$) and adolescents ($n = 50$) who were seen in a clinical setting. Diagnoses were based on RDC using the K-SADS. The most frequent comorbid disorder in both children and adolescents was separation anxiety (42% and 44%, respectively). Conduct disorder was comorbid in 16% of children and 14% of adolescents. However, unlike separation anxiety that did not show significant gender differences in its presentation, conduct disorders were only present in preadolescent boys, whereas in adolescents, a somewhat greater proportion of girls (17%) than boys (10%) had conduct disorder comorbid with major depression.

One of the most noteworthy investigations of psychopathology comorbidity in adolescents is a study conducted by Lewinsohn and colleagues (Lewinsohn et al., 1995; Rohde, Lewinsohn, & Seeley, 1991) in a western Oregon community. This study used diagnostic methods to evaluate a community sample of adolescents for *DSM-III-R* psychiatric disorders, incorporating two assessment periods approximately 14 months apart. Rohde et al. (1991) examined prevalence of current and lifetime depression and comorbidity in a sample of 1710 adolescents. There were 50 adolescents with a current diagnosis of major depression and 347 with lifetime prevalence of depression. There were 21 (42.0%) of the depressed youngsters who demonstrated one or more additional psychiatric disorders, with anxiety disorders (18%), disruptive behaviors (conduct disorder and oppositional defiant disorder) (8%), substance use (14%), and eating disorders (4%) present. For the lifetime estimates of comorbidity, 42.9% of adolescents with a lifetime diagnosis of major depression also had experienced one or more additional psychiatric disorders. In their 1995 (Lewinsohn et al., 1995) report on a sample of 1507 youngsters aged 14 to 18, there were 342 with a lifetime diagnosis of major depression. Of these adolescents, there were 67 with comorbid anxiety disorders, 78 with substance abuse disorder, and 36 with disruptive behavior. It should be noted that the authors did not include cases with other comorbid disorders, such as eating disorders and schizophrenia. Of the group with major depression, 205 youngsters did not demonstrate other psychopathology. Lewinsohn et al. (1995) examined the proportion of youngsters who were receiving treatment by the number of diagnoses. Of youngsters with a psychiatric diagnosis without comorbidity (i.e., pure cases) 24.8% were receiving treatment. There was a significant increase in the proportion of adolescents receiving treatment as a function of comorbidity (50.4% for two disorders and 65.9% for three or more disorders).

Another major study of comorbidity in children with depressive disorders is the longitudinal investigation of Kovacs and colleagues (Kovacs, 1990; Kovacs et al., 1984a, 1984b; Kovacs, Akiskal, Gatsonis, & Perrone, 1994; Kovacs, Gatsonis, Paulauskas, & Richards, 1989; Kovacs, Paulauskas, Gatsonis, & Richards, 1988) who studied a cohort of 104 children aged 8–13 presenting diagnoses of major depressive disorder ($n = 46$), dysthymic disorder ($n = 23$), combined major depressive disorder and dysthymic disorder (double depression; $n = 16$), and adjustment disorder with depressed mood. In this cohort, significant comorbid conduct and anxiety disorders were also noted.

5.17.7.1 Comorbidity and Biological Communalities

The mechanisms for comorbidity are probably quite complex, and are beginning to be hypothesized. For instance, Lam, Solyom, and Tompkins (1991) found similarities in seasonal symptom variation among bulimic patients to those found among persons with seasonal affective disorder and hypothesized that there may be a common neurobiological abnormality, possibly involving serotonergic dysfunction. Genetic predisposition has also been noted as a potential explanation for some patterns of comorbidity. Walters et al. (1992), using evidence from twin studies suggests that there may be a partial shared common genetic basis for bulimia nervosa and major depression. Mufson, Weissman, and Warner (1992) examined comorbid depression and anxiety in children of parents with major depression, major depression and panic disorder, and other disorders, finding evidence for familial transmission. Similarly, Paul (1988), in examining the comorbidity between anxiety disorders and depression and a range of biological aspects of these disorders, suggests that anxiety and depression may represent different phenotypes of a common neurobiological substrate.

5.17.7.2 The Range of Disorders Comorbid with Depression

Case reports have illustrated a wide-range of disorders that may co-occur with depression in children and adolescents, including: trichotillomania (Naylor & Grossman, 1991; Weller, Weller, & Carr, 1989); autism (Komoto, Usui, & Hirata, 1984); borderline personality disorder (Stone, 1981); and conversion symptom (Weller & Weller, 1983), the latter obscuring the depressive disorder.

Most research on the comorbidity of depression and other psychiatric disorders in children and adolescents has been based on clinical samples with a few noteworthy community-based studies, such as that of Lewinsohn and colleagues (1995). In the study of depression and its comorbidity, a particularly ubiquitous relationship with anxiety disorders has been evident and generated a tremendous amount of research and debate (Brady & Kendall, 1992; Kendall, Kortlander, Chansky, & Brady, 1992; King, Gullone, & Ollendick, 1990; Weissman, 1990). In addition to anxiety disorders, researchers have reported comorbidity of depression in youngsters with attention deficit disorder (Alessi & Magen, 1988; Biederman, Munir et al., 1987; Jensen et al., 1988), conduct disorders (Alessi & Magen, 1988; Kovacs, Paulauskas, et al., 1988; Puig-Antich, 1982), substance abuse (De Milio, 1989; Levy & Deykin, 1989), and eating disorders (Alessi, Krahn, Brehm, & Wittekindt, 1989).

5.17.7.3 Comorbidity with Other Internalizing Disorders and Problems

Depressive disorders, by their symptom definitions, share a number of features with other disorders such as eating disorders and anxiety disorders. By its definition, comorbidity refers to a different case as may occur when a relationship between two disorders is found as a function of shared symptoms alone. However, it may be that certain disorders also share various precursors or etiological factors that result in an increased risk for their co-occurrence. The disorders presented below were selected in large part as a function of the research literature. It is evident that other disorders may also show some level of comorbidity, but by their nature or incidence/prevalence have not been a major focus of study.

5.17.7.3.1 Anxiety disorders

Anxiety disorders represent a major domain of psychopathology and a wide range of clinical disorders. One of the earliest reports of childhood depression and other psychopathology focused on the relationship between school phobia and childhood depression. Agras (1959) described seven children aged 6–12 years who demonstrated school phobia, six of whom showed significant depressive symptoms. It is interesting to note that the comorbidity of depression and symptoms of anxiety was viewed by Agras (1959, p. 534) as similar "phenomenologically to the depressive disorders of adults."

School refusal or school phobia has continued to be linked or found comorbid with depression (Bernstein & Garfinkel, 1986; Naylor, Staskowski, Kenney, & King, 1994). In a study of 35 children with school phobia, Waldron, Shrier, Stone, and Tobin (1975) found that a significantly greater number of these youngsters manifested depression (56%) than a comparison group of children diagnosed as having other neuroses (26%). With a matched sample of 28 inpatient and 28 outpatient youngsters who were evaluated as school refusers, Borchardt, Giesler, Bernstein, and Crosby (1994) found a diagnosis of major depression in 85.7% of the inpatients and 46.4% of the outpatients, the only comorbid diagnosis that was significantly different in proportions between the two groups.

In a study of the comorbidity of depressive disorders with anxiety disorders, Kovacs, Gatsonis et al. (1989) reported that 41% of their sample of 104 youngsters with major depression and/or dysthymic disorder had an anxiety disorder at the initial (index) study episode of depression, with separation anxiety and overanxious disorder the most frequent comorbid diagnoses. In 19 of 30 participants with major depression the anxiety disorder predated the onset of depression. Strauss, Last, Hersen, and Kazdin (1988) found that 28% of 106 children and adolescents with a *DSM-III* diagnosis of an anxiety disorder had a concomitant diagnosis of major depression.

5.17.7.3.2 Eating disorders

A great deal of discussion and research has focused on the comorbidity and relationship between depression and eating disorders (Swift, Andrews, & Barklage, 1986). Rastam (1992) in a study comparing 51 adolescents with anorexia nervosa to a matched control group of school-based adolescents found that 69% of the former also met criteria for major depression or dysthymic disorder, compared to 10% of the school-based comparison group. They did not find clear evidence to suggest that depression was an antecedent of anorexia. Smith and Steiner (1992) found comorbid major depression in 53% of a sample of adolescent girls seen in an eating disorders clinic. In a six year follow-up of 23 anorexic youngsters, Smith, Feldman, Nasserbakht, and Steiner (1993) found a lifetime prevalence of major depression in 86.9% of the sample.

A significant study of comorbidity was presented by Herzog, Keller, Sacks, Yeh, and Lavori (1992) with 229 females seen in a treatment setting with anorexia nervosa ($n = 41$), bulimia nervosa ($n = 98$) and mixed anorexia nervosa and bulimia nervosa ($n = 90$) using RDC criteria for diagnosis. They found that major depression was the most common comorbid disorder. For the total sample, at least one affective disorder was found in 63% of the cases, with 41% (94 cases) manifesting major depression. Patients with both anorexia and bulimia demonstrated the highest rate of comorbidity with major depression (53%) in comparison to the other eating disorder groups, and 76% of this mixed group had at least one affective disorder. It is also of interest that the mixed group was younger in age than the other groups at onset of the eating disorder ($M = 17.5$, versus 19.1 for anorexia and 18.8 for bulimia).

In a school-based sample of 3287 adolescents in France, Ledoux, Choquet, and Manfredi (1993) found a relatively high rate of depressive symptom endorsement among youngsters who engaged in binge eating (20.2%) compared to non-binge eaters (6.3%) $\chi^2 = 45.06, p < 0.001$. There was also a gender difference, with a higher proportion of binge-eating girls reporting high levels of depressive symptoms (26.6%) compared to binge-eating boys (10.6%).

In addition to clinic and school-based studies, case studies have also reported comorbidity between eating disorders and depression. In a somewhat unique case report, Alessi et al. (1989) reported on a case of a nine-year-old girl with anorexia nervosa and major depression. The child was hospitalized for 10 weeks and received psychotherapy. Significant decreases in scores on the CDRS-R (from 76 at intake to 20 at week nine of treatment) and increases in weight from 52.5 pounds to 70 pounds at discharge were reported with the youngster maintaining this weight for two weeks. Although this case is considered rare, it does show that comorbidity of these disorders may have an early onset in some youngsters.

5.17.7.4 Comorbidity with Externalizing Disorders and Problem Behaviors

The comorbidity of depression with externalizing disorders is a significant area of research, with questions as to why such diverse forms of psychological disorders co-occur and what underlying mechanism may be responsible for this outcome. Such questions remain to be answered. For the present, the comorbidity of depression and conduct disorders, substance abuse, and attention-deficit hyperactivity disorder (ADHD) are examined.

5.17.7.4.1 Conduct disorder

There is a substantial literature base on the coexistence of depression and conduct disorder, the latter sometimes operationalized as juvenile delinquency. In the early 1970s, a number of investigators were identifying depression among adolescents seen in clinical settings for delinquent youth (e.g., Weinberg & van Den Dungen, 1971). Some of the studies discussed below were based on youngsters adjudicated as delinquent, the majority of whom we may assume meet criteria for conduct disorder, although this may not apply to all youngsters.

In a study using RDC diagnosis of depression in a sample of juvenile delinquents, Chiles, Miller, and Cox (1980) found 28 (23%) of a sample of 120 adolescents met criteria for major depression. Somewhat lower rates were reported by Alessi et al. (1984) who found 15.5% of a sample of 71 incarcerated juvenile offenders had a RDC diagnosis of major depressive episode and another 15.5% had a diagnosis of minor depressive disorder. An additional 8.5% were diagnosed having a major depressive disorder in remission. Kovacs, Paulauskas, Gatsonis, and Richards (1988) found that in their sample of 104 children, 17 (16%) had a comorbid conduct disorder at the time of the study initial (index) depressive episode, with another seven youngsters who received a diagnosis of conduct disorder during the course of the study and after remission of the index episode of depression. There were no differences in proportion of comorbidity between types of depressive disorders.

Kutcher, Marton, and Korenblum (1989) reported on the psychiatric morbidity of adolescents admitted to an inpatient psychiatric unit. After excluding four youngsters with conduct disorder without comorbid Axis I disorders, the authors found 26 of the remaining 96 adolescents had a conduct disorder comorbid with other Axis I disorders. Comorbid disorders to the conduct disorder included depression (five cases), bipolar disorder (eight cases), psychotic disorders (seven cases) and other disorders (six cases).

Within the same domain of disruptive behaviors, researchers have also found oppositional defiant disorder (ODD) comorbid with depression. Wenning, Nathan, and King (1993) found that 14 of 28 children (aged 6–13) seen in a clinical setting who had a diagnosis of ODD also met criteria for dysthymia. None of the children had episodes of major depression. The authors, in a retrospective examination of intake diagnoses, indicated that only one of the 14 children with ODD and dysthymia were so diagnosed at intake. The remaining 13 children were found to also have had dysthymia at intake, that had been overlooked and only identified by interviews with therapists who were given the opportunity to review *DSM-III-R* mood disorder criteria.

In a study of 56 child and adolescent psychiatric inpatients with major depressive disorder, Meller and Borchardt (1996) found 41% with comorbid conduct disorder. An examination of symptoms that differentiated between depression only and comorbid groups indicated that anxious mood was present to a greater extent in youngsters with depression only.

5.17.7.4.2 Attention deficit hyperactivity disorder

The coexistence of hyperactivity and depression in children has been noted since the 1970s, with a wide range in rates of comorbidity (Biederman, Newcorn, & Sprich, 1991). Brumback and Weinberg (1977) studied 223 children aged 6–12 years who were referred to an educational diagnostic center. Using Weinberg criteria for the diagnosis of depression, 136 children were depressed with 86 (63%) of these children also demonstrating hyperactivity. The authors noted that for some of the youngsters with depression and hyperactivity, their hyperactivity was somewhat episodic with depression, worsening during depressive episodes and decreasing as depression remitted.

Weinberg and Emslie (1991) described the diagnostic status of 100 children and adolescents referred to a pediatric neurology clinical setting, finding a diagnosis of ADHD in 63 youngsters. Of these 63 youngsters, 46 (73%) also had a diagnosis of depression, with the majority of these youngsters ($n = 40$) also manifesting developmental-specific learning disorders. The authors also noted that in a group of 65 children recently referred to their clinical setting who had a *DSM-III-R* diagnosis of major depression, 21 (32%) also had a diagnosis of ADHD, with the ADHD preceding the depressive disorders in all cases. Similarly, Biederman et al. (1994) in a study of 140 boys found major depression comorbid in 39 (27.9%) youngsters.

ADHD has also been noted in adolescents with bipolar disorder, with West, McElroy, Strakowski, Keck, and McConville (1995) finding eight (57%) of 14 bipolar patients with *DSM-III-R* mania or hypermania demonstrating a comorbid ADHD. In all cases, the ADHD predated the onset of bipolar disorder, by an average of six years. The prior presentation of ADHD and the time between onset of disorders is consistent with ADHD typically identified in childhood, and bipolar disorder often emerging during adolescence.

5.17.7.4.3 Substance abuse

When studying comorbidity in adolescents, a relatively common finding is the coexistence of substance abuse and psychiatric illness. Depressive disorders are among the most studied disorders comorbid with substance abuse (e.g., Bukstein, Brent, & Kaminer, 1989), although conduct disorders and substance abuse tend to show higher rates of comorbidity (Kaminer, Tarter, Bukstein, & Kabene, 1992). The study of substance abuse and depression in young people is a very important domain of research as well as clinical attention. Substance abuse is a major problem in adolescents. In the study of psychopathology accompanying substance abuse, depression and conduct disorders appear to be the most concomitant disorders (Kaminer, 1991).

As noted, there have been numerous reports of depressive disorders concurrent with substance abuse. Kashani, Keller, Solomon, Reid, and Mazzola (1985) reported on 16 cases of double depression as well as another 12 youngsters with either major depressive disorder or dysthymic disorder in a sample of 100 adolescents with substance abuse disorders. The comorbidity of affective disorders and other psychiatric disorders in an inpatient psychiatric sample of 156 adolescents aged 13–18 with substance abuse was examined by Bukstein, Glancy, and Kaminer (1992) who found an affective disorder in 51.3% of the sample, second to conduct disorder which was found in 70.5% of the youngsters. Of the mood disorders identified, 30.7% demonstrated major depression, 5.1% dysthymia, 7.7% bipolar, and there were 9.0% of the sample who were comorbid with adjustment disorder with depressed mood. A significant number (22 of the 48) of the youngsters with major depression and substance abuse also had an additional diagnosis of conduct disorder. Overall, nearly 27% of the sample of substance abusers also had concurrent diagnoses of conduct disorder and an affective disorder. In determining the timing of the onset of disorders, in the major depression–substance abuse only group, the substance abuse preceded the onset of major depression by one year.

In a study of 52 inpatient adolescent substance abusers, Hovens, Cantwell, and Kiriakos (1994) found major depression and dysthymia present in 25% and 33% of youngsters, respectively. Of particular interest was the examination of the temporal sequence of substance abuse and psychiatric disorders. The authors found that substance abuse preceded the cases with major depression by about $3^1/_2$ years. A different picture was evident for youngsters with dysthymia, with dysthymia emerging prior to the onset of substance abuse in approximately 53% of the cases.

Stowell and Estroff (1992) examine the discharge diagnosis of 226 consecutive adolescent admissions (aged 12–18 years) to two inpatient treatment settings for substance abuse problems. Mood disorders were found in 61% of substance abusers, with 18% comorbid with major depression, 34% dysthymia, 9% bipolar, and 12% double depression with both major depression and dysthymia. Based on self-report data, the authors suggested that depression preceded the regular use of substances in 68% of the sample. However, this is not to suggest a causal pathway. Stowell and Estroff also noted that significant psychosocial stressors—such as sexual and physical abuse, parental substance abuse, divorce and separation, death of family members or close friends, and other stressors—may be contributory factors. In such cases, substance abuse became greater after such psychosocial stressors and exacerbated depressive symptoms.

Similar rates of depression among substance abusers were reported by Deykin, Buka, and Zeena (1992) with a sample of 223 chemically dependent adolescents in a residential treatment setting. They found 24.7% of the sample met *DSM-III-R* criteria for major depression, with a significantly higher proportion of females (48.2%) compared to males (16.9%) with major depression. With regard to temporal order of onset, 35.2% of those with depression developed chemical dependence following the depression, with chemical dependence preceding depression in 43.1% of the sample and occurring at the same time in 21.6% of the sample of comorbid youngsters. Other investigators studying youngsters with substance abuse have reported rates of major depression of 35% (DeMilio, 1989) with presence of any affective disorder noted as high as 78% (McKay, Murphy, Maisto, & Rivinus, 1992).

5.17.7.5 Diagnostic Overshadowing

A significant issue in the study of comorbidity is that of diagnostic overshadowing. In the Wenning et al (1993) investigation, the majority (93%) of the children with comorbid ODD and depression were not identified as being depressed as well as oppositional at intake. Likewise, other externalizing disorders such as ADHD may mask a depressive disorder or, as Weinberg and Emslie (1991) suggest, children referred for ADHD may not be systematically evaluated for the presence of additional psychopathology. A similar recommendation was made by McClellan, Rubert, Reichter, and Sylvester (1990) who found that a significant number of children who had an anxiety or depressive disorder also demonstrated attention deficit disorder (ADD). These authors suggested that clinicians evaluating children referred for ADD should consider the potential for a comorbid or primary affective disorder.

The above are useful examples of diagnostic overshadowing. Such cases may most frequently occur when an internalizing disorder such as depression is masked (in an overt sense) by the extremes and behavioral excesses found in most externalizing disorders.

5.17.7.6 Comorbidity Summary

The extensive findings of comorbidity among children and adolescents with psychiatric disorders, including depressive disorders, has important implications for our understanding of depressive disorders in young people, as well as approaches to identification, treatment, and prevention.

It is evident that when we study comorbidity within select clinical samples, such as in groups of youngsters referred to an eating disorders clinic or substance abusers in a chemical dependency treatment setting, rates of comorbidity will differ from those found in large-sample studies of depressed youngsters. Furthermore, data regarding comorbidity based on clinic samples may be biased and represent somewhat inflated values as a function of increased treatment seeking due to greater distress caused by two or more disorders, increased likelihood of referral, and other selection biases (du Fort, Newman, & Bland, 1993). Likewise, certain types of comorbidity may be seen to a greater extent in treatment and other clinical settings. For instance, depression comorbid with externalizing disorders, such as conduct disorder, ADHD, or substance abuse, is at increased risk for referral or identification by others. To more accurately understand the comorbidity between two disorders, data from large, representative samples drawn from the general population are needed.

A question in the study of comorbidity is that of the temporal relationship between disorders. That is, do consistent findings suggest that one disorder commonly predates another, and if so, does this indicate a predisposition of one disorder to another? As described in this chapter, a few studies have examined this by investigating the onset of disorders. For the most part, findings suggest that in the cases of certain comorbid disorders that may develop during certain developmental periods, there is little evidence to suggest that the initial disorder is a precursor to the emergence of the second disorder. For instance in the case of bipolar disorder with comorbid ADHD, the ADHD which typically is diagnosed in childhood predates the onset of bipolar disorder which tends to emerge during adolescence and young adulthood. For other disorders, the onset in reference to the index episode of depression may occur prior, during, or subsequent to the depressive episode.

From the above studies, it is quite clear that many youngsters with depression also manifest other forms of psychopathology, both of internalizing and externalizing phenomenology. Toward understanding the nature of comorbidity, investigators have begun to examine the course and potential causal pathways of depression and comorbid psychopathology (Capaldi, 1991; Caron & Rutter, 1991; Loeber, Russo, Stouthamer-Loeber, & Lahey, 1994).

The examination of the coexistence of other psychopathology and depression in children and adolescents is important for a number of reasons. As Alessi and Magen (1988) noted, the existence of multiple disorders may in some individuals lead to the development of a depressive disorder. Likewise, the co-occurrence may create an increased stress response with psychological and biological interactions. Clearly the biopsychosocial approach is critical when examining comorbidity.

5.17.8 SUMMARY AND CONCLUSIONS

In this chapter a biopsychosocial perspective was presented as a framework for understanding some of the complexities inherent in our knowledge of depression in children and adolescents. The biopsychosocial model provides a scaffold for examining the features, correlates, and etiologies of depression in young people. In this regard, it can be seen and understood that depression in children and adolescents is a complex interaction of social and environmental factors, predispositions, cognitive and behavioral skills and competencies, biological vulnerability factors, and other individual difference variables.

The importance for understanding the nature, identification, and treatment of depression in children and adolescents is best understood by the basic fact that depressed youngsters feel intense psychological distress and misery. Depressed children and adolescents face daily impairments in psychological functioning and often perceive that there is no hope for improvement. Research suggests that for many depressed youngsters, the long-term outcome is poor, with the likely development of more severe pathology in adulthood (Harrington, 1996; Kovacs, 1996a, 1996b).

The past two decades have provided professionals with a remarkable amount of information on depression as an internalizing disorder in children and adolescents. This has resulted in the development of measures that are now used by clinicians for the identification of depressed youngsters, as well as the publication of empirically tested treatment manuals for the provision of psychotherapy. Advances in the understanding of psychobiological correlates of depression in children and adolescents, and advances in pharmacological interventions also provide insight into the basic nature of this disorder in young people. Of domains in which basic and applied research needs to be conducted, the understanding of the developmental nature of depression in children remains an area of critical importance. Research and theoretical descriptions on the developmental nature of depression in children have begun to appear. However, there are numerous questions specific to the expression and syndromal description of depression in children and adolescents that still need to be answered.

Likewise, we are just beginning to understand the course of depression, although much of this is based on a few well-conceived and executed studies. However, given the heterogeneity of depressive disorders and the myriad etiological and interactive variables that come into play, we will require extensive investigation across numerous samples to determine how depressive disorders, both syndromal and subsyndromal, affect children and adolescents.

5.18.1 INTRODUCTION

Although suicide is rare in childhood, the rates of adolescent (15–19 year-olds) suicide almost tripled from 1950 to 1980. From 1980 to 1992, the rate increased by another 28.3%, from 8.5 to 10.9 per 100 000 (Centers for Disease Control [CDC], 1995a). The sharp rise in adolescent suicide is of significant concern. Beyond the emotional toll on the survivors and the tragic loss of a life so young, there are also considerable economic costs related to suicide. It has been estimated that each youth suicide results in approximately $432 000 worth of lost economic productivity (Weinstein & Saturno, 1989). Suicide attempts that do not result in death are also a significant public health problem. They occur at a very high rate (7–10% of adolescents report that they have attempted suicide) and a significant number (approximately 2–3%) of suicide attempters receive costly medical care following their attempts (CDC, 1995a).

This chapter summarizes many of the factors that contribute to adolescent suicide and suicide attempts. Adolescent suicide completers and attempters form separate, but overlapping groups. Thus, it is necessary to describe both. The first portion of this chapter discusses factors associated with completed and attempted suicide. The second portion of the chapter describes the clinical evaluation of suicide attempters. A bio-psychosocial model is utilized to synthesize the multiple factors that may affect outcome among suicide attempters. Understanding these factors also aids in the development of comprehensive and effective treatment plans for this high-risk group of adolescents. The final section discusses treatments for adolescents with suicidal ideation and adolescents who have attempted suicide.

5.18.2 PHENOMENOLOGY

Suicidal behavior includes both thoughts and actions. For some adolescents, a suicide attempt is the result of an impulsive act in the face of significant stress. For others, suicide attempts follow a course from passive suicidal ideation, to serious consideration of suicide as an option, followed by active planning. Suicidal thoughts may vary in frequency, intensity, and duration. The time course prior to a suicide attempt can be quite variable, ranging from many months of suicidal ideation to only several days or even hours. A suicide attempt may hold a particular meaning for either an individual or family; for example, it may be an indirect way of communicating distress or a way to receive attention within a family. Completed suicides may occur in adolescents who did not actually want to die but rather made an impulsive attempt using lethal means. Thus, the psychological characteristics associated with adolescent suicidality vary significantly, and no one pattern of psychopathology adequately describes adolescents who experience suicidal ideation, make a suicide attempt, or complete suicide.

5.18.3 DIAGNOSTIC FEATURES

Suicide and attempted suicide are not psychiatric disorders, but rather, symptoms of emotional distress which may be associated with certain psychiatric disorders such as depression. Consequently, there are no true diagnostic criteria. However, there is a great deal of confusion in the literature regarding what constitutes a "true" suicide attempt, and even suicidal ideation. What degree of ideation is necessary before a clinician or researcher considers an adolescent a suicide ideator? Similarly, does there have to be a certain level of suicidal intent or sufficient medical lethality for a suicide attempt to be considered a "true" suicide attempt? A variety of terms have been used to describe suicidal behavior. Standard nomenclature for suicidal behavior does not currently exist, which makes it difficult to interpret empirical findings. Reference to terms such as self-injury, self-mutilation, parasuicide, and suicide threats is common, and the term "suicidal gesture" is used in clinical notes and sometimes in research reports. The latter term typically refers to a suicide attempt of low medical lethality. This chapter uses the terms "completed suicide," "attempted suicide" and "suicidal ideation."

Several characteristics of a suicide attempt are pertinent to determining its severity. These include the intensity of suicidal ideation prior to the attempt, method of attempt, the precipitant of the attempt, and suicidal intent accompanying the attempt.

5.18.3.1 Ideation

The degree of suicidal ideation accompanying an attempt may be a marker of the seriousness of a suicide attempt. Spirito, Overholser, and Vinnick (1995) found that more than half of a sample of 203 adolescent suicide attempters demonstrated clinically significant levels of ideation on the Suicide Ideation Questionnaires (Reynolds, 1987): 13.8% of the sample scored in the 99th percentile and 43.3% scored in the 95th percentile or above. However, a significant number of adolescents did not report very high levels of suicide ideation, suggesting either an impulsive attempt or denial of their suicidal state.

5.18.3.2 Method of Attempt

The method of attempting suicide is not typically a useful indication of severity because the large majority of adolescents attempt suicide by drug overdose (Spirito, Brown, Overholser, & Fritz, 1989). Compared to adults, adolescents have limited access to other more lethal means of suicide which may account for the overrepresentation of overdoses. Because of the availability of medical care in most Western nations, overdoses are rarely fatal. The potential for a medically serious suicide attempt increases when prescription drugs are available, regardless of whether or not the drugs have been prescribed for the adolescent or another family member. Suicide attempts by other means, for example, hanging or firearms, often warrant greater concern and consideration by clinicians. However, clinicians should not minimize the seriousness of suicide attempts by overdose before investigating other associated features of the suicide attempt.

5.18.3.3 Precipitant of the Attempt

The precipitant of a suicide attempt is another important factor which seems to be comparable across nations. In the United States, stress related to parents, school, friends, and boyfriend/girlfriend relationships are the most common precipitants (Spirito, Overholser & Stark, 1989). In Britain, very similar findings have been reported (Hawton & Fagg, 1992). It is, therefore, important for clinicians not to minimize a suicide attempt because the precipitating problem is a common everyday event. Adolescents should be interviewed regarding the precipitant to the suicide attempt in order to thoroughly understand the significance of the particular stressor in the adolescent's life.

5.18.3.4 Intent

The intent of a suicide attempt appears to be important in terms of understanding differences in the severity of suicide attempts. Spirito et al. (1995) reported that only a minority of suicide attempters report extensive planning (4%), writing a suicide note (14%), or performed final acts in anticipation of their death prior to the attempt as assessed using the Suicide Intent Scale (Beck, Schuyler, & Herman, 1974). Many adolescents expect their attempt to cause their death (31%) and a significant number are ambivalent or sorry to have survived their attempt (57%).

A factor analysis of the Suicide Intent Scale revealed three aspects of suicidal intent specific to adolescent suicide attempters (Spirito, Sterling, Donaldson, & Arrigan, 1996). One factor, labeled Expected Outcome, included items that address the expectations, purpose, seriousness, and lethality, as well as ambivalence about living following a suicide attempt. A second factor, Isolation Behaviors, consisted of isolation at the time of the attempt, timing of attempt, precautions against discovery, and acting to gain help. A third factor, Planning Activities, included items about degree of premeditation, planning, and final acts. The findings of the factor analysis suggest that it may be more useful, when evaluating adolescent suicide attempters, to examine subjective factors, particularly Expected Outcome, and selected objective factors, such as those found in the Planning Activities factor, rather than the overall level of suicidal intent.

The distinction between impulsive, unplanned attempts, and planned attempts is important in assessing the seriousness of suicide attempts. Brent (1987) found that a group of suicide attempters with high levels of hopelessness had made premeditated and highly lethal attempts compared to the unplanned and impulsive attempts made by adolescents who did not report high levels of hopelessness. In a general hospital sample, Brown, Overholser, Spirito, and Fritz (1991) found that about one-third of the suicide attempts could be classified as planned and two-thirds could be described as impulsive. Those adolescents who planned a suicide attempt were more hopeless and depressed and experienced greater suicidal ideation than the other impulsive attempters. Slap, Vorters, Chaudhuri, and Centor (1989) found that a lack of impulse control differentiated adolescent suicide attempters from a group of nonpsychiatrically hospitalized adolescents. There also appear to be gender differences in impulsivity in that male adolescent suicide attempters are more often described as displaying impulsive behavior than female suicide attempters (Marks & Haller, 1977). Because impulsivity does not characterize every adolescent suicide attempter, it can be used as a variable to classify a subgroup of these attempters.

5.18.4 PREVALENCE

Internationally, the youth suicide rate varies but is consistently one of the highest causes of death during adolescence. Diekstra and Golbinat (1993) reviewed statistics on suicide rates reported to the World Health Organization's (WHO) mortality data bank. The countries with the highest youth (15–24 years) suicide rates included Sri Lanka (62.3 per 100 000 in 1986), Finland (25.1 per 100 000 in 1991), Switzerland and Austria (16.2 per 100 000 in 1991), and Canada (15.0 per 100 000 in 1990). Suicide is the third leading cause of death among youth age 15–24 years old in the United States (National Center for Health Statistics [NCHS], 1993). The absolute number of deaths by suicide among adolescents in the US is fairly small (usually between 2000 and 2500 adolescents per year).

The statistics on suicide rates have generally been considered to be an underestimate of the true incidence due to misclassification of deaths that might be suicides (e.g., single car crashes, as well as failure to report deaths as suicides due to social stigma). The magnitude of the discrepancy between actual suicide rates and the reported statistics has been a subject of considerable debate (Males, 1991). The reporting of a suicide is related to several factors including whether mental illness preceded the death, who certifies the death, and the means of death (e.g., single car crash vs. gunshot wound). If there has been a true increase in the rate of adolescent suicide, as many suggest, one reason may be that adolescents from larger birth cohorts appear to be at higher risk for suicide than those in smaller cohorts (Holinger & Offer, 1987). This may reflect the fact that fewer opportunities and increased competition are more evident in larger cohorts than smaller ones, and may result in hopelessness and eventual suicide.

Systematic data collection of suicide attempt rates is rare. Estimates of adolescent suicide attempts in the United States range from approximately 8% in a study conducted in Oregon (Lewinsohn, Rhode, & Seeley, 1993) to 8.6% in a national survey of a representative sample of students in grades 9–12 collected by the Centers for Disease Control (1995a) using the Youth Risk Behavior Surveillance System. Based on 1988 data, Holinger (1990) estimated that over 15 000 adolescents between the ages of 10 and 19 attempted suicide and received medical attention. Several studies have attempted to calculate rates of suicide attempts seen in emergency departments. A rate of 140 per 100 000 was calculated based on suicide attempts in a suburban Chicago area (Christoffel, Marcus, Sagerman, & Bennett, 1988), while a rate of 316.8 per 100 000 was calculated in a suburban county of Atlanta (Birkhead, Galvin, Meehan, O'Carroll, & Mercy, 1993). Diekstra (1993) estimates a lifetime prevalence of attempted suicide for adolescents in the international community ranging from 2% to 20%. Because of the manner in which these statistics are collected, and because there is no central registry of suicide attempts, it is difficult to compare rates across countries, and changes in the rates over time are also difficult to interpret.

The WHO/EURO multicenter study collected data on attempted suicide in 15 European centers (Platt et al., 1992). Suicide attempt rates ranged from 72 per 100 000 in Leiden to 426 per 100 000 in Helsinki for men between the ages of 15 and 24 years. For women between the ages of 15 and 24 years, the rates ranged from 112 per 100 000 in Guipuzeon to 763 per 100 000 in Pontoise. The overall European rate for 15 to 19 year-old males was 106 per 100 000 and 323 per 100 000 for 15 to 19 year-old females. The highest adolescent rate was 911 per 100 000 in Pontoise followed by 791 per 100 000 in Szeged.

As regards suicide ideation, females report much higher rates than males in most countries of the world. Data collected in 1993 using the Youth Risk Behavior Surveillance Survey in the United States supported these findings (CDC, 1995b). Across all racial and ethnic groups, females reported more suicidal ideation than males.

5.18.5 ETIOLOGY: RISK FACTORS

There is no definitive underlying cause for suicide. However, there are a number of demographic (e.g., gender and race), psychiatric (e.g., certain mental disorders such as depression and conduct disorder; prior suicide attempts), biological (e.g., dysfunction of the serotoninergic system), and socio-environmental (access to lethal methods, e.g., firearms; exposure to suicidal behavior) factors which increase the risk of suicide. These risk factors will be reviewed in turn.

5.18.5.1 Gender

In all age groups, females attempt suicide more often than males, but males complete suicide more often than females. According to Centers for Disease Control data collected in the United States in 1992 (1995a), the suicide rate for adolescent males was 18.4 per 100 000 compared to a rate of 3.7 per 100 000 for adolescent females. Diekstra (1993) examined the suicide rates in 19 countries between 1970 and 1986. The rate for men increased across all age groups with a mean increase of 70% in the suicide rates in adolescents and young adults. For young women the increase was closer to 40%. One potential reason for the difference in suicide rates between males and females may be method preference. Males are more likely to use highly lethal suicide attempt methods whereas females are more likely to use less lethal methods, particularly drug overdoses (Sigurdson, Staley, Matas, Hildahl, & Squair, 1994). Although some drug overdoses can be lethal in high doses, most suicide attempts by drug overdose are reversible if brought to medical attention within a reasonable amount of time. In India and in Southeast Asia, where medical care is not always readily available, the majority of suicides are committed by women by overdose (Shaffer, 1988).

The difference in suicide methods between males and females has been linked to stereotypic sex role behavior. That is, men tend to delay expressing their distress and during this period of delay, find more lethal methods for suicide attempts, while females express their affect in a more immediate and sometimes impulsive fashion. There is some evidence to support this contention. When male adolescent suicide attempters were compared to female adolescent suicide attempters on measures of depression, hopelessness, suicidal ideation, and suicidal intent, the only differences between sexes were that males reported more final acts in anticipation of death and a greater degree of planning than the female attempters (Spirito et al., 1993).

5.18.5.2 Race

In the United States, adult Caucasians commit suicide more frequently than adult African-Americans, typically at a 3:1 ratio (NCHS, 1993). However, since the mid-1960s the suicide rate for adult African-American males has nearly tripled, and has doubled for adult African-American females. This increase has also been noted in adolescents, particularly males. For African-American adolescent males, the rate increased from 5.5 per 100 000 in 1980 to 14.8 per 100 000 in 1992, an increase of 164%. The suicide rate rose from 1.6 per 100 000 in 1987 to 1.9 per 100 000 in 1992 for African-American adolescent females, an increase of 19% (CDC, 1995a).

These differences in suicide rates by race have not been well studied. Gibbs and Hines (1989) hypothesized that there are protective factors in the African-American population, such as strong maternal family ties or church and fraternal organizations that increase social support and cohesion, thus decreasing the rate of suicide. Others note that African-American males die by other violent means besides suicide more frequently than whites, which may account for the larger rates of suicide in Caucasians than African-Americans (Gibbs & Hines, 1989). The dramatic increase in the 1980s of African-American adolescent suicide rates has led some to speculate that if culture is a protective factor, the rates of suicide may be equalizing because social factors which promote deculturalization exist (Shaffer, Gould, & Hicks, 1994).

Hispanic youth have lower rates of suicide than Caucasians, although suicide was the third leading cause of death for Hispanic youth in 1990 (NCHS, 1993). Gender differences in suicidal behaviors seem to be less prominent among Hispanic teenagers (Spirito et al., 1993).

Very high rates of suicide have been estimated among Native American adolescents (26.3 per 100 000) (US Congress, Office of Technology Assessment, 1990). This is due, at least in part, to the much larger proportion of adolescents and young adults among Native Americans than Caucasians. In addition, the suicide rates vary greatly among different tribes (McIntosh, 1983–84). One troubling example of the problem of suicide among Native American adolescents is the Zuni tribe. The suicide rate among Zuni adolescents rose steadily from 5.6 per 100 000 in 1957 to 32.2 per 100 000 in 1989.

5.18.5.3 Psychiatric Disorders

Certain psychiatric disorders are common among adolescents who complete suicide. Approximately 90% of adolescents in the New York City area who completed suicide in one study had a prior psychiatric diagnosis (Shaffer et al., 1996). These findings are comparable to those reported previously in Pittsburgh (Brent et al., 1988) and in Finland (Marttunen, Aro, Henriksson, & Lonnqvist, 1991). The most common psychiatric diagnosis in the New York City study (Shaffer et al., 1996) was Mood Disorder, occurring at a rate (61%) somewhat higher than that reported in the Finnish national study (51%) and in Pittsburgh (49%). Bipolar disorder was uncommon in both the Finnish study and the New York City study. In the New York City study, there was also a much higher percentage of Disruptive Behavior Disorders among the adolescents than the Finnish national study.

Bipolar Disorder, Affective Disorder with comorbidity (especially Attention Deficit Disorder, Substance Abuse, and Conduct Disorder), a lack of previous mental health treatment, and availability of firearms in the home differentiated 27 adolescents who had committed suicide from 56 psychiatric inpatients who had seriously considered or attempted suicide (Brent et al., 1988). Blumenthal and Kupfer

(1986) believe that the coexistence of the antisocial and depressive symptoms are a particularly high risk combination for adolescent suicide. A high rate of substance use in the male adolescents who completed suicide was found in the New York City study (Shaffer et al., 1996), where approximately 60% of the male adolescent suicide victims had one of the following risk factors: prior suicide attempt, mood disorder, and substance/alcohol use. Depression and substance abuse were the most common risk factors in Canadian youths age 15 to 24 years old (Sigurdson et al., 1994). Alcohol plays a prominent role in suicides among Alaskan natives (Hlady & Middaugh, 1988) and is particularly prevalent in tribes which have high adolescent suicide rates.

Some adolescents evidence no psychiatric disorder prior to suicide completion (Apter et al., 1993). These adolescents have been described as perfectionistic and rigid (Apter et al.), and more likely to have prior suicidal behavior, legal, or disciplinary problems, and family psychopathology (Brent, Perper, Moritz, Baugher, et al., 1993). Thus, it seems likely that pathology exists in this group, but is more covert and/or denied by the family.

There is limited research regarding personality characteristics and disorders among suicidal adolescents. In Finland, 32% of adolescents in a sample of completed suicides were diagnosed with a personality disorder (Marttunen et al., 1991). Antisocial Personality Disorder among males and Borderline Personality among both males and females were the most common diagnoses reported. One-third of 58 suicides between the ages of 15 to 19 years old in Sweden were diagnosed with Borderline Personality Disorder by psychological autopsy methods (Runeson & Beskow, 1991).

Psychiatric disorders have also been investigated among suicide attempters and ideators. There has been interest in determining whether adolescent suicide attempters have a higher rate of Borderline Personality Disorder than other adolescents. However, there have only been a few studies in this area using adolescent samples. Pfeffer, Newcorn, Kaplan, Mizruchi, and Plutchik (1988) examined factors associated with suicidal behavior in a chart review of the clinical diagnoses of 200 consecutively admitted adolescent psychiatric inpatients and found a positive association between suicidal behavior in adolescent females and Borderline Personality Disorder. Brent et al. (1993) reported on increased evidence of borderline personality disorder or traits among psychiatrically hospitalized suicide attempters compared to psychiatric controls who had never been suicidal.

Depression has also been implicated in suicidal ideation and attempts (Garrison, Jackson, Addy, McKeown, & Waller, 1991). Mood disorders, particularly depression, may be precursors to different types of suicidal behavior. However, it appears that other related difficulties (e.g., substance abuse or conduct problems), are often seen in combination with depressed mood. Substance use is also related to suicide attempts (Pfeffer et al., 1988) and is considered a risk factor for both attempted and completed suicide because it can affect multiple domains of functioning, (i.e., affective, cognitive, social, and behavioral; Shaffer, 1988). For example, alcohol may lower inhibition and lead to more impulsive and dangerous behaviors that result in death. When combined with depressed mood, substance abuse significantly increases the risk of suicide in vulnerable groups.

5.18.5.4 Prior Suicide Attempts

One of the best predictors of completed suicide is a previous suicide attempt (Spirito, Brown, et al., 1989; Diekstra, 1989). In their review of the literature, Shaffer and colleagues (1988) concluded that in approximately 20% of all suicides completed by male adolescents and 33% of all suicides completed by females, a history of a prior suicide attempt is evident. Among adolescents, male suicide attempters are much more likely than females to eventually complete suicide (Goldacre & Hawton, 1985; Otto, 1972). A previous attempt by active means, such as hanging or shooting, has also been found to be predictive of later completed suicide (Otto, 1972). In addition, it has been estimated that adolescents who attempted suicide are 8.1 times more likely to reattempt suicide than those who have never made a suicide attempt (Lewinsohn et al., 1993).

5.18.5.5 Biological Factors

The endocrine and neurotransmitter systems have been the major focus of research to determine whether biological correlates of suicide exist. Most of this research has been conducted with adults and is quite complex and methodologically complicated. Findings have been based on postmortem tissue analyses, brain chemistry, cerebrospinal fluid, and neuroendocrine correlates. Major findings are available in detailed reviews (Rifai, Reynolds, & Mann, 1992; Roy, 1994) and are briefly outlined in this chapter.

Serotonin is the major neurotransmitter that has been linked to suicidal behavior. Low levels of serotonin (5-HIAA) and 5-hydroxytryptophan (5-HTP) have been reported among suicide attempters and found to be related to impulsivity and aggressive behavior in both depressed and non-depressed samples (Roy, 1994; Traskman-Bandz et al., 1993). Serotonergic changes appear to be most strongly related to impulsive aggression and violent suicides (Mann et al., 1992). In another study (Nordstrom et al., 1994), low CSF levels of 5-HIAA were related to increased suicide risk following attempted suicide in depressed patients.

Several studies report that suicidal behavior is associated with low CSF concentrations of the dopamine metabolite, HVA. However, these findings seem to be applicable to depressed patients only. In a five year follow-up study (Roy, DeJong, & Linnoila, 1989), dopaminergic activity was shown to be related to repeat suicide attempts among depressed patients. The mechanism by which serotonin levels affect suicidal behavior is unknown, but environmental factors and other variables are most likely involved because many individuals with low CSF concentrations do not attempt suicide.

Although more research is needed to clarify the differential roles of various receptor sites and their relation to suicide, reduced serotonin levels are related to repeat suicide attempts, impulse control, and aggression in depressed and nondepressed samples. It also appears that the reduced activity of serotonin may be related to a higher risk of death by suicide following an unsuccessful suicide attempt. Although this area has promise, a lumbar puncture is necessary to gather a specimen of CSF, which limits its applicability to clinical care. There is a serotonin metabolite level that can be measured by urine sample, which may ultimately provide useful information regarding suicide risk. However, at present biological factors are not routinely assessed when evaluating suicidal behavior.

5.18.5.6 Method of Suicide: Firearms

In the United States, suicides are most commonly completed by using firearms (Holinger, 1990). In 1992, 64.9% of all suicides among people less than 25 years old were by firearms (CDC, 1995a). Hanging was the second most common suicide method. For 15–19 year-olds, the rate of suicide by firearms increased 81% between 1980 and 1992, probably reflecting greater access to firearms by adolescents. Guns have been shown to be twice as prevalent in the homes of adolescents who complete suicide compared to adolescents who either attempt suicide or have other psychiatric disorders (Brent et al., 1991). However, the method of storing guns has no effect on suicide (Brent et al., 1991). When firearms are available in the home, suicidal adolescents will actively kill themselves at a rate 75 times higher than when firearms are not available at home (Brent et al.). The most common method of attempting suicide among adolescents is by drug overdose. Estimates range between 75% and 95% of subjects across a number of studies conducted in the United States (Spirito, Brown, 1989) and Britain (Hawton & Fagg, 1992).

5.18.5.7 Exposure

Another potential risk factor for completed suicide is previous exposure to suicidal behavior in the family or in the peer group. Shaffi, Carrigan, Whittinghill, and Derrick (1985) found that adolescents who complete suicide are significantly more likely to have been exposed to suicidal behavior in parents, relatives, or friends. The risk of completing suicide increases with having a family member who has committed suicide. Higher rates of suicide and suicide attempts have been noted in the relatives of suicide completers compared to community controls (Brent et al., 1994).

Not only does exposure lead to increased risk of completed suicide, but the risk of attempting suicide increases significantly if there is a family history of suicide attempts (Sorenson & Rutter, 1991). Adolescents who report that a peer attempted or completed suicide display higher levels of depression and more frequent suicidal behavior themselves than those with no such exposure (Hazell & Lewin, 1993). However, Brent, Perper, Moritz, Baugher et al. (1993) examined the psychiatric sequelae of the suicide of a peer and found that suicide attempt rates did not differ between those exposed and those unexposed. The exposed group demonstrated more suicidal ideation and depression than the unexposed group. At three-year follow-up, the exposed group had an increased incidence of depression, anxiety, and Post-traumatic Stress Disorder compared to the unexposed group, but the two groups did not differ on suicidal behavior (Brent, Moritz, Bridge, Perper, & Canobbio, 1996).

The findings with respect to familial clustering of suicide and suicide attempts indicate that a genetically linked biological mechanism such as the serotonergic system may be involved. Alternatively, exposure may allow suicidal behavior to be modeled by family members who attempt or complete suicide. There are a number of studies (discussed in Section 5.18.7.7) Au:X-ref.OK?

in which family dysfunction increases the risk of suicidal behavior. Studies designed to differentiate the role of genetic and/or psychological mechanisms have yet to be conducted.

Adolescents may also be exposed to suicide indirectly via television or the news media. Several studies have demonstrated that a prominent report of a suicide in the media leads to an increase in suicides, particularly among young people, for one to two weeks following the news coverage (Shaffer, 1988; Phillips & Carstensen, 1986). In addition, exposure to a violent death, regardless of the means (e.g., homicide or car crash) increases the likelihood of subsequent suicides among youth in the community. It has been found that victims of high social status, deaths motivated by revenge, and failure of the media to report a victim's prior psychiatric disturbance increase the risk of imitation (Davidson, 1989; Davidson & Gould, 1989). Consequently, the Centers for Disease Control (1988) have developed guidelines for the media on reporting suicides.

There is also conflicting data regarding the relationship between fictional suicide stories and subsequent imitative suicides. Gould and Shaffer (1986) found increased suicide rates among adolescents in the New York City area two weeks before and two weeks after four television movies about suicide were broadcast. However, when the same movies were shown in California and Pennsylvania, albeit by only one station, which limited the audience and the impact, the findings were not replicated (Phillips & Paight, 1987).

5.18.6 DEVELOPMENTAL COURSE

The rates of suicide vary across development. Although rare, suicide rates among children 10 to 14 years old in the United States have been estimated to be on the rise, increasing two and a half times between 1970 and 1986, from 0.6 to 1.5 per 100 000 (US Bureau of the Census, 1990). As stated previously, the rate for adolescents increased from 8.5 to 10.9 per 100 000 between 1980 and 1992 (CDC, 1995a). Various investigators have emphasized the need to examine developmental risks and protective factors for suicide. Characteristic of this approach is an emphasis on the relation between suicidal behavior and developmental factors, for example, sociocognitive functioning, as opposed to chronological age. The range of developmental skills within a particular age group may vary greatly or fluctuate as a function of emotional distress (Jacobson et al., 1995).

Up to 1997, limited empirical work has examined suicide from a developmental perspective. However, McDowell and Stillion (1994) delineated several commonalities and differences in suicide across the lifespan. The commonalities include biological, psychological, cognitive, and environmental factors. With respect to biological factors, the serotonin hypothesis and gender differences described have been shown to transcend all ages (McDowell & Stillion, 1994). Psychological factors such as depression, low self-esteem, and hopelessness also contribute to suicide across the life span. Cognitive factors related to suicide across development include depressogenic thought patterns, such as cognitive rigidity, all-or-none thinking, and overgeneralization. In addition, perfectionism has been found to be a risk factor regardless of age (Hewitt, Flett, & Turnball-Donovan, 1992; Hewitt, Newton, Flett, & Callander, 1997). Regarding environmental factors, exit events (e.g., parental divorce), all types of abuse, and family stressors have been found to play a role in suicide for both children and adults, as has the presence of a means for completing suicide. Moreover, the precipitants of suicidal acts in young children (Pfeffer, Conte, Plutchik, & Jerrett, 1980) and adolescents (Spirito et al., 1989) are similar.

McDowell and Stillion (1994) also outlined suicide risk factors unique to young children and to adolescents. Risk factors for children younger than 15 years of age include impulsivity, a sense of inferiority, the expendable child syndrome, an immature view of death, and extreme levels of persistent family turbulence. With respect to impulsivity, suicidal behavior in young children has been found to be more violent and impulsive; for example, jumping or running out in front of a car (Joffe & Offord, 1983). Pfeffer et al. (1980) reported that jumping was the most common means of attempt among 6 to 12 year-old outpatient psychiatry patients. A sense of inferiority was used by McDowell and Stillion (1994) to refer to the Eriksonian concept of industry, or the need to develop confidence and positive self-regard. This concept is relevant to the findings in the literature regarding the relation between suicide and low self-esteem (e.g., Stillion, McDowell, & Shamblin, cited in McDowell & Stillion, 1994). The "expendable child syndrome" is a concept that refers to children whose parents communicate low regard and even hostility toward them to the extent that children believe they are expendable, which is related to the wish to die.

Concrete operational thinking, common in latency-aged children, has implications for the meaning and understanding of suicide in young children. Carlson et al. (1987) reported that although children between 8 and 12 years of age contemplate suicide, they have difficulty conceiving of the circumstances that might lead one to commit suicide and plan to carry it out. Similarly, young children's understanding of death, causality, and reversibility have important implications for suicidal behavior in this group (Jacobson et al., 1995). In addition, family problems have long been reported to be a more important factor for younger than older suicidal children because of the dependence of younger children on adult caregivers for survival (Otto, 1972). A particular family factor identified as a risk factor for children under 12 years of age is the presence of suicidal behavior in their parents (Pfeffer et al., 1980). With respect to suicide attempts, attempters younger than 14 years of age have been found to be more likely to leave a suicide note prior to an attempt and use hanging vs. ingestion as a means to attempt suicide (Garfinkel, Froese, & Hood, 1982).

Risk factors specific to adolescent suicide include the adolescent's mood state, the inability to develop a sense of identity, egocentrism, risk-taking behaviors, and social isolation (McDowell & Stillion, 1994). As discussed earlier, psychiatric diagnoses, particularly depression, conduct disorder, and substance abuse, are significant risk factors for suicide during adolescence. In addition, adolescents who have no sense of identity may not have the necessary level of self-competence to cope with the stressors that confront them during this period. Self-esteem has been found to be inversely related to suicidal ideation and behavior in both adolescent psychiatric patients and normal high school controls (Overholser, Adams, Lehnert, & Brinkman, 1995). Similarly, cognitive changes characterized by a renewed period of egocentrism may increase feelings of self-consciousness and consequently overgeneralization, such as that reported in depressive cognition patterns.

It has been suggested that a sense of invulnerability characterizes adolescents, and this has been hypothesized to lead to increased risk taking. Empirical studies of the relation between risk-taking behaviors and suicide have not yet been reported. Some studies have examined the role of interpersonal relationships and suicidal behavior. Peer relationship difficulties are one of the most common precipitants of suicide attempts in adolescence (Spirito et al., 1989), and suicidal adolescents have been found to be socially isolated and have poor peer relationships (King, Raskin, Gadowski, Butkus, & Opipari, 1990; Spirito et al. 1989). Adolescents are also more likely than younger children to mutilate themselves and make a planful suicide attempt (McDowell & Stillion, 1994).

5.18.7 CONCEPTUALIZATION AND CLINICAL FORMULATION OF ATTEMPTED SUICIDE

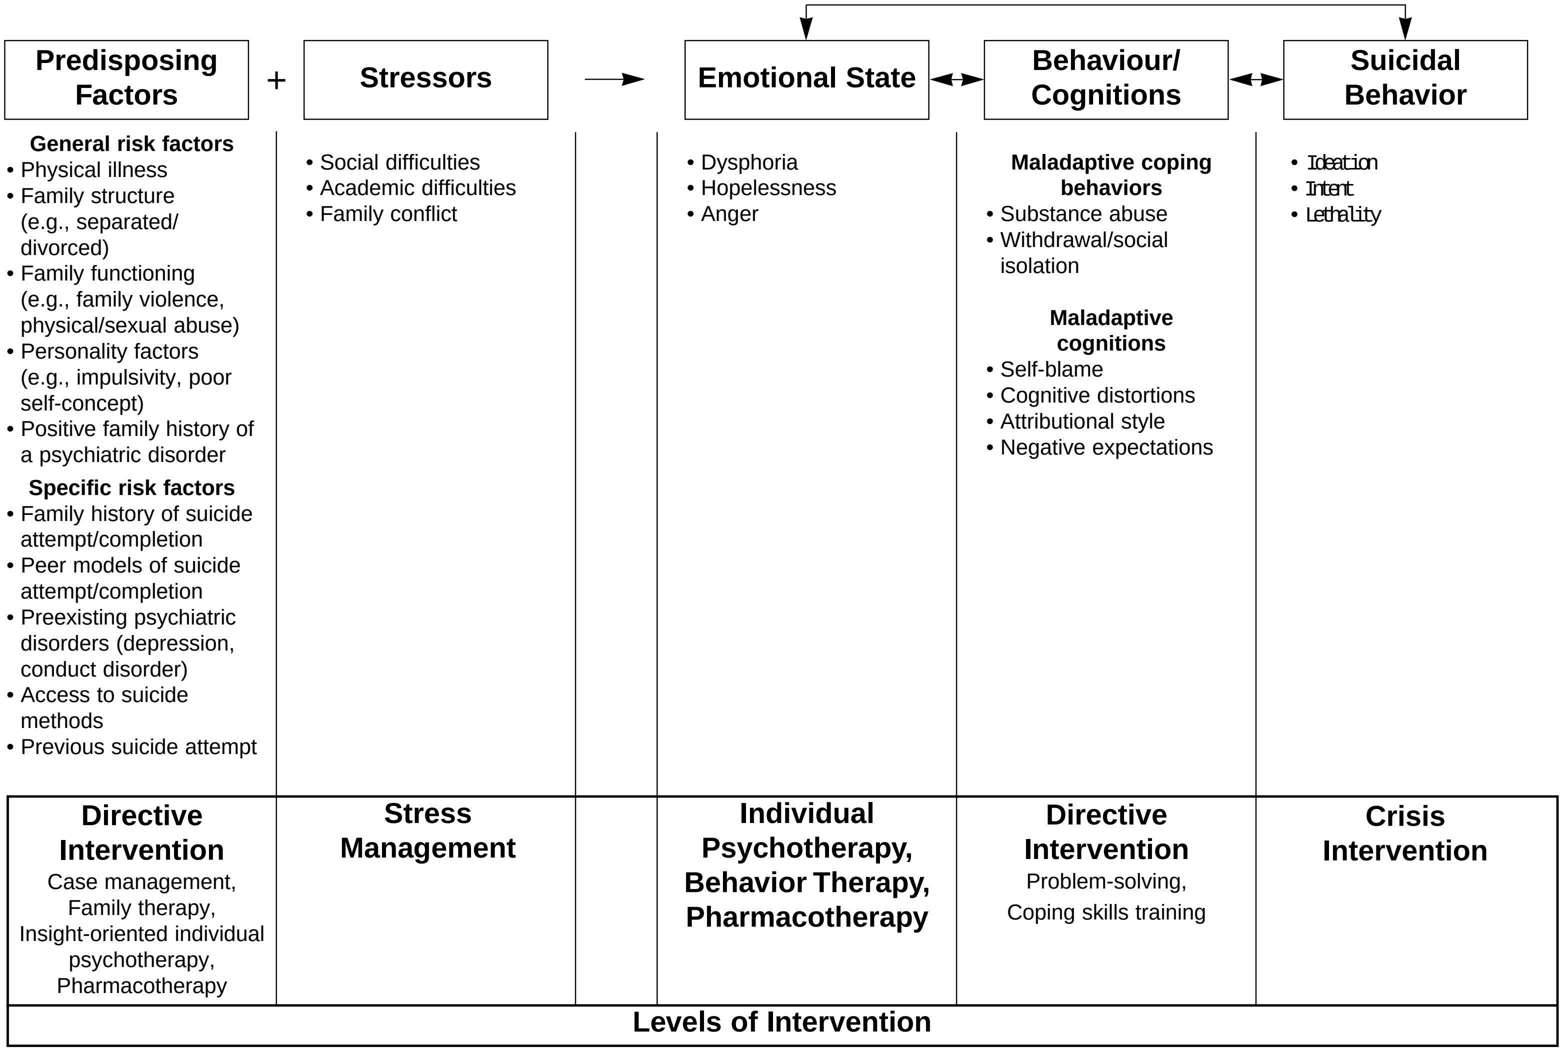
There is no standardized treatment for adolescent suicide ideators and attempters. Consequently, it is important to perform a comprehensive assessment in order to target in treatment those deficit areas that may trigger further survival behavior.

5.18.7.1 Multimodal Assessment

There are a number of important factors to consider when evaluating an adolescent who has just attempted suicide. One assessment model can be seen in Figure 1. This conceptual model is similar to a number of other models that have been hypothesized in the literature, and is based on the assumption that suicidal individuals display cognitive, behavioral, and emotional deficits which increase their risk of suicidal behavior at times of increased stress. Both the adolescent and his/her parents/guardians should be interviewed to complete the assessment.

Only one assessment model to date has been tested empirically. Based on epidemiologic data collected with a large sample of high school students, Lewinsohn, Rohde, and Seeley (1996) postulated a model which includes the constructs of psychopathology, environmental factors, interpersonal problems, and physical illness which affect cognitions/coping, leading to suicidal behavior. Using structural equation modeling, psychopathology had the strongest (0.34) direct effect on suicidal behavior. Physical health and environmental factors had small, but statistically significant, direct effects. All four constructs had statistically significant indirect effects on suicidal behavior via cognitive/coping style. Cognitive/coping style also had a direct effect on suicidal behavior (0.20). Tests of this model with clinical populations would be a useful contribution to the literature.

Assessment of the suicide attempter at the time of the attempt is critical in formulating an adequate treatment plan. Assessment should be conducted with both the adolescent and family members. Suicidal ideation preceding the attempt, as well as the reasons for the suicide attempt, must be investigated. The first goal of this evaluation is to determine whether the adolescent requires a psychiatric admission, usually based on continued suicidal ideation, a major psychiatric disorder that cannot be treated initially as an outpatient, or psychological or family factors that may place the adolescent at continued risk for immediate self-harm or a reattempt. The following areas are particularly important to assess: suicidal intent



Predisposing Factors
+
Stressors
Emotional State
Behaviour/ Cognitions
Suicidal Behavior
General risk factors
• Physical illness
• Family structure (e.g., separated/ divorced)
• Family functioning (e.g., family violence, physical/sexual abuse)
• Personality factors (e.g., impulsivity, poor self-concept)
• Positive family history of a psychiatric disorder
Specific risk factors
• Family history of suicide attempt/completion
• Peer models of suicide attempt/completion
• Preexisting psychiatric disorders (depression, conduct disorder)
• Access to suicide methods
• Previous suicide attempt
• Social difficulties
• Academic difficulties
• Family conflict
• Dysphoria
• Hopelessness
• Anger
Maladaptive coping behaviors
• Substance abuse
• Withdrawal/social isolation
Maladaptive cognitions
• Self-blame
• Cognitive distortions
• Attributional style
• Negative expectations
• Ideation
• Intent
• Lethality
Directive Intervention

or reason for the suicide attempt; current coexisting stressors; preexisting psychiatric disorders; family history, particularly of suicidal behavior; previous suicidal behavior; self-stated coping strategies and social support; an evaluation of the risk of an immediate reattempt; and attitudes of the adolescent and family towards further mental health treatment (Hawton, 1986). These factors are elaborated on in the following sections.

5.18.7.2 Attempt Characteristics

The intent of the suicide attempt maybe the most important characteristic of the attempt to assess in clinical formation. Data from adolescents (Spirito et al., 1989) suggest that two aspects of suicidal intent, making plans prior to a suicide attempt and expected negative outcome, are the most important factors in determining high risk adolescents.

5.18.7.3 Emotional State

An adolescent's mental status at the time of the attempt, as well as premorbid psychological factors (particularly depression, hopelessness, and anger) are important to assess, both in terms of their individual impact and their contribution to a diagnosis of a specific psychiatric disorder. Depressed mood has been implicated in many studies of adolescent suicide attempters. Spirito et al. (1989) reviewed the literature and found very high rates of depressed affect among attempters, ranging from 30% to 82%, across studies in psychiatric inpatients, outpatients, and emergency department settings. The lowest rates were found in suicide attempters who were medically hospitalized.

Hopelessness may contribute to suicidal ideation and behavior above and beyond depression. Hopelessness refers to a negative attitude about future events, including a global expectation of negative future occurrences. Spirito, Williams, Stark, and Hart (1988) found higher levels of hopelessness among adolescent suicide attempters than among either nonsuicidal adolescents in an outpatient psychiatric clinic or normal control subjects. In a separate study, Spirito, Overholser, and Hart (1991) found higher levels of hopelessness in adolescent suicide attempters than in nonsuicidal psychiatrically hospitalized adolescents. Some studies (e.g., Robbins & Alessi, 1985) have reported that hopelessness among adolescents is associated with the number of suicidal gestures, the seriousness of suicidal intent, and the medical lethality of a suicide attempt. Hopelessness has also been shown to have a stronger relationship to suicidal behavior than other factors, such as family dysfunction (Levy, Jurkovic, & Spirito, 1995). Gender effects on hopelessness (i.e., females report greater levels of hopelessness than males) have also been reported (Cole, 1989; Spirito, 1991). However, several studies have found comparable levels of hopelessness among adolescent suicide attempters and depressed adolescents (Brent, Kolko, Allan, & Brown, 1990; deWilde, Kienhorst, Diekstra, & Wolters, 1993).

Another important variable related to adolescent suicide attempts is anger. Anger has been shown to be more strongly related to suicidal ideation and behavior than depression (Cairns, Peterson, & Neckerman, 1988; Choquet & Menke, 1989). Repressed anger has also been shown to be highly correlated with hopelessness (Brown et al., 1991). When compared to normal adolescents, suicide attempters report an increased incidence of experiencing anger as well as higher levels of internalized anger (Lehnert, Overholser, & Spirito, 1994). Many adolescents report significant anger prior to their attempt (Hawton, O'Grady, Osborn, & Cole, 1982; Withers & Kaplan, 1987). These angry feelings may be expressed via verbal outbursts, but at other times the anger is repressed. Anger has also been associated with the seriousness of the suicide attempt (Gispert, Wheeler, Marsh, & Davis, 1985). In several studies, the strongest predictor of future suicidal tendencies and suicide reattempts was the level of anger at the time of the initial attempt (Myers, McCauley, Calderon, & Treder, 1991). At times, the anger and irritability so prominent in adolescent suicide attempters may be a symptom of depressive illness. At other times, anger and irritability may also be indicative of a conduct disorder. Indeed, a large proportion of childhood suicide attempters have been shown to exhibit assaultive and aggressive behavior independent of depression (Pfeffer, Plutchik, & Mizruchi, 1983). Thus, the origin of the aggressive and angry feelings must be differentiated on an individual basis.

5.18.7.4 Cognitive Variables

A negative attributional style (i.e., likelihood of attributing undesirable events to oneself or others, to unstable factors, or to global causes) has been found to be related to suicidal behavior in adults. Evidence in adolescents is more limited. The results of two studies of adolescents showed that suicide attempters were more likely than the nonsuicidal psychiatric patients to attribute good events to global causes and negative events to stable aspects of the environment (Rotheram-Borus, Trautmen, Dopkins, & Shrout, 1990; Spirito, Overholser et al., 1991). Although further study is needed, these data suggest that a maladaptive attributional style may be more related to overall level of psychopathology than specifically to suicidal behavior among adolescents.

Another cognitive factor which has been seen studied in suicidal adolescents is problem solving. Problem-solving deficits are important to investigate because the data have direct implications for the types of interventions that may be appropriate for this high-risk group. Female adolescent suicide attempters have been distinguished from nonsuicidal psychiatrically disturbed adolescents by their poorer interpersonal problem-solving ability and maladaptive attributional style (Rotheram-Borus et al., 1990). Sadowski and Kelley (1993) found that suicide attempters reported poor problem-solving orientation as well as less adequate problem-solving skills in general, than a comparison group of psychiatric patients and normal high school students. In addition, these adolescent suicide attempters reported less cognitive responding and deficits in initiating the problem-solving process than the other groups when confronted with problem situations. Suicidal children have also been found to use fewer active cognitive coping strategies than controls (Asarnow, Carlson, & Guthrie, 1987). Orbach, Rosenheim, and Mary (1987) compared psychiatrically hospitalized children with suicidal ideation and behavior to children with chronic medical illnesses and normal controls on the ability to generate alternative solutions to situations involving life and death. The suicidal children generated fewer alternatives than the normal or the chronically ill children. Among the suicidal children, those most attracted to death were least capable of generating effective alternative solutions. In a study comparing inpatient suicide attempters to controls, there was no difference in their ability to generate solutions to standardized personal problems (Wilson et al., 1995). However, when asked about how they coped with their most recent severe stressor, suicide attempters reportedly used fewer coping strategies and more maladaptive coping strategies than the controls.

Perfectionism is another cognitive characteristic which has been investigated in regard to adolescent suicidal behavior. Both self-oriented and socially prescribed perfectionism were found to be positively related to hopelessness in adolescent psychiatric inpatients (Hewitt et al., 1997). However, only the relation between socially prescribed perfectionism and suicidal ideation attained significance. Moreover, only socially prescribed perfectionism contributed unique variance to suicidal ideation when the effects of age, gender, self-oriented perfectionism, and hopelessness were controlled.

In summary, cognitive deficits such as poor problem solving and cognitive distortions appear more frequently in a significant portion of adolescent suicide attempters compared to non-suicidal adolescents. It is unclear whether these are temporary deficits evident at the time of acute stress, or more enduring characteristics. In either case, it is important for clinicians to identify and intervene in these deficit areas when they present.

5.18.7.5 Maladaptive Coping Strategies

Social isolation and avoidance behavior are maladaptive coping strategies reported by adolescent suicide attempters. More adolescent suicide attempters report using social withdrawal when faced with a problem than normal control subjects (Spirito Overkolser, et al., 1989). However, the use of social withdrawal among adolescent suicide attempters is similar to that found among nonsuicidal psychiatrically hospitalized adolescents (Spirito, Francis, Overholser, & Frank, 1996). Both groups reported using social withdrawal as a maladaptive coping strategy. These findings suggest that it is important for clinicians to address avoidance behavior. For example, adolescents who attempt suicide maybe similar to nonsuicidal adolescents in the sense that they attempt to use a number of coping strategies prior to the suicide attempt. However, they may use more maladaptive cognitive strategies and at a certain point, withdraw from social contact, which may increase the risk of a suicide attempt. This may be a sequence effect; adolescent suicide attempters may initially use adaptive coping strategies, then move on to maladaptive strategies, and finally withdraw prior to an attempt.

Attachment behavior has also been investigated as a precursor to social withdrawal. In a sample of both inpatient and outpatient adolescent psychiatric patients, 86% had attachment-related trauma when they were young (Adam, Sheldon-Keller, & West, 1996). These traumatic family experiences, including separation and abuse, may affect the development of attachment behavior, which may be a mediating mechanism for suicidal behavior, especially among female adolescents (Adam et al., 1996).

Substance use and abuse can be considered another maladaptive coping behavior. Studies in the US report significant rates of substance abuse ranging from 23% to as high as 42% among adolescent suicide attempters (Spirito, Brown et al., 1989). Work by Hawton & Fagg (1992), found elevated rates (39% males, 21% females) of consumption of alcohol a few hours before the attempt among British suicide attempters, but rates were not as high as typical rates reported in the US. In a large survey of high school students, alcohol use was associated with an increased suicide attempt rate, particularly among Caucasian adolescents (Adcock, Nagy, & Simpson, 1991). For Caucasian adolescents, the suicide attempt risks increased from 9% to 27% while among African-Americans it increased from 10% to 21%. Substance use, if it is of a chronic nature, can lead to significant psychosocial problems which eventually result in a suicide attempt. If substance use precedes a suicide attempt, it may interfere with problem solving and thus be a proximal factor to the suicide attempt.

5.18.7.6 Physical and Sexual Abuse

A history of physical or sexual abuse has been associated with suicidal behaviors in a number of studies. In a survey of almost 4000 predominantly white adolescents in a suburban/rural area, attempted suicide was reported by 4.7% of the physically-abused students, 5.1% of the sexually-abused students, and 9.2% of students who reported both physical and sexual abuse (Hibbard, Ingersoll, & Orr, 1990). Garnefski, Dieskta, and de Heus (1992) compared a sample of predominantly Caucasian high school students with a history of suicidal behavior to high school students with no such history. Of the female attempters, 51% reported a history of physical abuse and 32% had experienced sexual abuse. Of the females who did not attempt suicide, 24% reported a history of physical abuse and 7% reported sexual abuse. Of the male attempters, 22% had experienced sexual abuse compared to 2% of the nonattempters. This study did not include truant or dropout students, who may have an even higher incidence of physical and sexual abuse. A comparison of adolescent suicide attempters with depressed and nondepressed adolescents with no history of suicide attempts revealed that suicidal adolescents were more likely to report a history of sexual abuse (33%) than depressed (21%) or nondepressed adolescents (5%) who had not attempted suicide (deWilde et al., 1992). More depressed individuals (29%) reported physical abuse than suicide attempters (23%) or nondepressed adolescents (7%).

Deykin, Alpert, and McNamara (1985) examined adolescent suicide attempters who were identified following an emergency department visit and a matched comparison group of adolescents treated for medical conditions unrelated to suicide attempts. The suicide attempters were three to six times more likely than the comparison group to have had contact with state social services departments for an abuse-related incident. No information regarding reasons for social service involvement was available. The relationships between prior physical or sexual abuse and subsequent health-risk behaviors and suicide attempts were examined in a nonclinical sample of 600 high school students (Riggs, Alario, & McHorney, 1990). Those students who were victims of previous sexual maltreatment were three times more likely to have attempted suicide and those students with a history of physical maltreatment were five times more likely than those without a history of maltreatment.

Psychiatrically-hospitalized adolescents categorized as attempters, ideators, or nonsuicidal (i.e., those admitted for reasons other than suicide attempts and with no current suicide ideation) have been studied as to the effects of abuse (Shaunesey, Cohen, Plummer, & Berman, 1993). Females were more likely than males to have histories of both types of abuse, or sexual abuse alone, and females with past sexual abuse had a higher frequency of suicide attempts than females with no history of sexual abuse. In addition, adolescents with a high frequency of abuse (i.e., 10 or more events) had made significantly more suicide attempts.

5.18.7.7 Family Functioning

A number of studies have shown higher rates of family disturbance in suicide attempters compared to psychiatric controls (Mitchell & Rosenthal, 1992) and the severity of suicidal intent has been related to the degree of family dysfunction (Brent et al., 1990). Suicidal psychiatric inpatient adolescents and suicidal high school students report more distress and family dysfunction than nonsuicidal high school students (Adams, Overholser, & Lehnert, 1994). In a sample of high school students, family dysfunction influenced suicidal behavior indirectly through depression (Martin, Rozanes, Pearce, & Allison, 1995). In a large study of high school students, adolescents who reported a history of a suicide attempt also reported more frequent stresses related to their parents and more physical abuse, runaways, and family disruption than those who had not had previous attempts (Wagner, Cole, & Schwartzman, 1995).

Stressful life events as triggers of suicidal behavior have been of interest to many clinicians and researchers. Adams, Overholser, and Spirito (1994) examined both intrafamilial and extrafamilial life events. Hospitalized adolescent suicide attempters reported the loss of a family member due to death or divorce more often than high school controls (Adams, Overholser, & Spirito, 1994). Adolescent suicide attempters also reported a greater number of "exit events" such as parental divorce and chronic life stressors compared to nonsuicidal adolescents. Suicidal ideation was directly related to stressful life events among the female suicide attempters. The number of exit events was positively related to hopelessness and suicidal ideation among adolescent females. Although suicide risk seems to increase when elevated levels of stressful events exist, a high degree of family cohesion may mediate the effects of these stressful events (Rubenstein, Heeren, Housman, Rubin, & Stechler, 1989).

5.18.8 PSYCHOSOCIAL TREATMENTS

Treatment for adolescent suicidal behavior is quite varied and there is no one standard treatment approach for this group. A number of clinical articles have addressed the treatment of suicide ideators, focusing mainly on the management of the acute suicidal episode with little emphasis on ongoing treatment. A limited number of articles have been written on the treatment of adolescents following a suicide attempt. The majority of this work has also focused on short-term management of the adolescent following the suicidal crisis. Finally, interventions that focus on adolescents that have psychiatric disorders common to suicidal behavior, such as depression (e. g., Lewinsohn, Clarke, Hops, & Andrews, 1990), might also be considered as treatment approaches for adolescent suicidal behavior.

5.18.8.1 Suicide Ideators

Fremouw, de Perczel, and Ellis (1990) have outlined in great detail the principles for managing a suicide ideator. In particular, four principles are advocated: therapeutic activism, restoring hope, delaying of suicidal impulses, and environmental interventions. In regard to therapeutic activism, increasing the availability of the therapist during the suicidal crisis, working directly with the adolescent on problem solving and, when necessary, directing the adolescent and parents in how to manage a suicidal crisis are recommended (Fremouw et al., 1990). By actively working with the adolescent on how to solve problems and by taking one problem at time and generating solutions, the therapist can help to restore hope in what appears to be a hopeless situation. With adolescents, there are often acute conflicts with a family member, particularly parents. It is important for the therapist to actively assist in resolving the conflicts among family members at least for the short term and emphasize that the adolescent can make it through the current stress no matter how painful it seems. Environmental interventions are often necessary, such as working with the family on coping with adolescent suicidal behavior. It is important to involve parents in actively monitoring the adolescent's behavior. At the same time, removing pills and/or firearms from the home is very important. Finally, prior to the completion of a session, it is important for the therapist to work with the adolescent and their family on structuring the time between sessions to minimize the possibility of repeat attempts.

One particularly helpful problem-solving technique in managing suicide ideators has been described by Schneidman (1985). When confronted with a suicidal client, Schneidman suggests that the therapist and the patient write down a list of what might be done in the situation, including committing suicide. Then the therapist asks the patient to rank order the options from the most difficult and fatal (i.e., suicide) to the least difficult solutions. The therapist then begins to discuss the least difficult and painful solutions until the adolescent and the therapist find a solution, even a partial solution, that is acceptable to the adolescent. Schneidman contends that this approach has a calming effect on the adolescent because the therapist is helping to outline alternatives that the adolescent, due to cognitive restriction, was unable to generate. By discussing various options and their pros and the cons, progress is made because suicide is no longer the only solution.

5.18.8.2 Suicide Attempters

Adolescent suicide attempters have a significantly higher reattempt rate and risk of eventual completed suicide than adolescents who have not previously attempted suicide (Lewinsohn, Rohde, & Seeley, 1994). In 1997, there are no standard interventions for adolescent suicide attempters. Rather, intervention is typically developed on an individual basis, according to the symptoms occurring at the time of the suicide attempt.

The large majority of adolescents who attempt suicide can be treated effectively as outpatients. However, treatment noncompliance is particularly problematic among adolescent suicide attempters. Spirito et al. (1992) followed adolescent suicide attempters for three months after they were evaluated in an emergency department and discharged to outpatient care and found that 18% never attended an outpatient appointment, 11% went only once, 3% went twice, and 23% only went to three or four sessions. Even more striking are the results obtained by Trautman, Stewart, and Morishima (1993) indicating that adolescent suicide attempters drop out of outpatient psychotherapy at a much faster rate than nonsuicidal adolescents. Suicide attempters attended a median of three sessions before dropout, while nonsuicidal adolescents attended approximately 11 sessions.

This high rate of dropout of adolescent suicide attempters from psychotherapy suggests that clinicians who are evaluating adolescents immediately after a suicide attempt should take certain steps to ensure that outpatient therapy is accomplished following discharge. These include setting a specific date and time for the follow-up appointment; thoroughly explaining the reasons for continued outpatient care; explaining why therapy is important in the long run; and reviewing the likely goals and length of outpatient therapy (Jellinek, 1978). The adolescent's and their parents'/guardians' expectations for therapy should also be reviewed. Where resistance or hesitancy is noted, the clinician should address these problems. For example, if there is concern that the parents will not be able to get the adolescent to attend therapy, then problem-solving steps and potential alternatives to ensure the adolescent receives therapy should be reviewed with parents. In order to enhance compliance, it is preferable to discuss brief treatment (e.g., four sessions) with the option of continuation based on progress during that time. Asking adolescents and their parents to attend four treatment sessions before making a decision about further ongoing psychotherapy may be the most realistic approach to enhancing treatment compliance. Setting a specific time limit on psychotherapy has been shown to be more useful in ensuring treatment attendance than more open-ended treatment contracts (Sledge, Moras, Hartley, & Levine, 1990). As a final step, prior to discharge after a suicide attempt, the clinician might generate several potential stressors and ask how the adolescent would cope with those stressors if they were encountered. A directive, problem-solving approach will help the adolescent, particularly when discharged into a stressful situation. This type of "emergency plan" should focus on practical steps the adolescent should take if any suicidal feelings reemerge.

In developing a treatment plan for adolescent suicide attempters, therapists must rely on guidelines derived from either theoretical considerations or clinical care. Empirically-based guidelines specifically for suicide attempters are not available. In the initial therapy sessions with someone who has recently attempted suicide, a crisis intervention plan needs to be activated. The therapist must be continuously available, limit access to suicide methods, reestablish a no-suicide agreement if necessary, and ensure that the adolescent is not socially isolated, either from peers or from family. While managing the crisis using these guidelines, the therapist must also try to understand the reasons for the suicidal behavior and establish a working alliance with the adolescent in order to both reduce the risk of further suicidal behavior and maintain the adolescent in treatment (Berman & Jobes, 1991). Adolescents should be prepared, for example via role playing, for situations that may arise in the future that may elicit suicidal feelings. This approach can help prepare them for difficult circumstances as well as reduce the possibility of relapse.

The exact nature of treatment will vary according to the adolescent's presenting problems, the training and theoretical orientation of the therapist, and the adolescent's reactions to therapy. In general, however, there are a number of principles of psychotherapy with suicidal clients which should be observed no matter what the specific nature of treatment. In addition to those described above, these principles include maintaining an empathic but objective view of the suicidal adolescent, thoroughly understanding the motives of the suicidal behavior, continual reassessment and modification of hopelessness, assessment and modification of cognitive rigidity which impairs problem-solving, and education of the adolescent's family regarding suicide and suicidal behavior (Blumenthal & Kupfer, 1986). Once the crisis has passed, the feelings of depression and hopelessness associated with the suicidal behavior may begin to be addressed. The therapist can move from understanding the emotions that accompanied this suicidal behavior to specific problem-solving techniques that help to generate more effective ways of coping with life stressors as well as additional suicidal feelings that may arise in the future. In addition, after a short course of treatment, occasional booster sessions to help suicidal adolescents have some continuing contact with a therapist and review coping skills may be helpful in preventing additional suicidal behavior.

Although empirical data does not exist, several specific treatment modalities have been suggested for use with suicide attempters. First, cognitive therapy has been suggested as a possible treatment of choice for suicide attempters because it is highly structured and systematic. The cognitive distortions often evident in adolescent suicide attempters can be addressed directly using such a treatment approach. One goal of treatment is to help the adolescent become more aware of the relationships between their thoughts, emotions, and behaviors. Adolescents can begin to monitor their thoughts that lead to depressive cognitions and begin to challenge the validity of negative thought patterns (Bedrosian & Epstein, 1984). A number of cognitive techniques specifically useful for suicidal persons have been described (Freeman & Reinecke, 1993). These include reattribution of blame for the suicide precipitants, "decatastrophizing" (re-evaluating whether the adolescent is overestimating the "catastrophic" nature of their problems), making a list of pros and cons in regards to the circumstances precipitating the suicidal behavior, listing options and alternatives, "scaling" the severity of the events (e.g., from one to 100) to prevent the adolescent from conceptualizing everything as "black and white," and thought stopping.

One cognitive approach advocated by numerous clinicians as being helpful for suicidal patients is problem solving. As discussed above, therapy with suicidal adolescents often involves active teaching of new coping skills. Problem-solving therapy can help teach adolescents new ways of conceptualizing their problems and generating alternatives, because these adolescents often are unable to generate alternatives on their own. A description of the problem-solving approach with adolescent suicide attempters can be found in Brent and Kolko (1990). One focus of problem-solving is on interpersonal areas. Adolescents may at times use suicide attempts in a coercive manner for interpersonal gain. Thus, interpersonal problem solving to improve peer and family relationships can be effective. One behavioral approach to complement problem-solving efforts is to use social skills training for those adolescents who are particularly deficient in basic social skills which affect their peer relationships. Group therapy has been suggested as a potentially useful modality for treating adolescent suicide attempters. The group format can be helpful in teaching social skills and problem-solving skills as well as in reducing isolation and stigma associated with suicidal behavior.

Family therapy is often advocated as a means to deal with the intense conflict within families which can lead to maladaptive actions, including suicidal behavior (Richman, 1979). Family therapy itself helps to shift focus away from the individual adolescent, which in turn allows conflictual issues which have contributed to the development of the suicidal behavior to be investigated (Richman, 1979). Family therapy programs emphasizing communication and problem-solving skills that have been used with other high-risk adolescents (e.g., Robin, 1981) are applicable to work with families of adolescent suicide attempters. A six session cognitive-behavioral family therapy approach for adolescent suicide attempters has been described by Rotheram-Borus, Piacentini, Miller, Graae, and Castro-Blanco (1994). This treatment approach is very structured and includes a number of activities designed to create a positive atmosphere among family members, teach problem-solving strategies to all family members, shift the emphasis of the family to a concept of difficult situations as opposed to difficult family members (i.e., the adolescent), and enhance the confidence of the family members in mental health treatment. A number of cognitive techniques such as restructuring and reframing are used in this treatment approach as well as behavioral contracting, therapist modeling, and role playing. Outcome data are still being collected on this promising treatment approach.

5.18.8.3 Secondary Prevention of Suicidal Behavior in High-risk Groups

Another approach to reducing suicidal behavior is to study well-defined groups that are known to be at higher risk for suicide. These groups, such as runaways, Native Americans, adolescents who come from families with a history of suicidal behavior, adolescents who have been diagnosed with major depression, and surviving friends of adolescents who have completed suicide, often have significantly higher rates of suicidal behavior in their immediate or more distant history compared to other adolescents. Thus, interventions designed to help the overall functioning of high-risk groups may also have an effect on suicidal behavior. Unfortunately, few studies have specifically observed the effects of interventions on suicidal behavior. Rotheram-Borus and Bradley (1991) reported on an intervention with suicidal runaways seen in community shelters that resulted in reduced rates of suicide attempts when compared to the agency rate prior to implementation of the program.

Intervention programs specifically tailored for Native Americans must be based on an understanding of the cultural values and social factors that affect suicidal behaviors. For example, an intervention for Native American adolescents who attempted suicide and were living at a boarding school has been described (Ward, 1984). Tribal elders conducted group discussions about leadership in an attempt to reduce suicidal behavior. Interventions have also been conducted with Native Americans who have been incarcerated, in residential alcohol treatment programs, or school dropouts. However, these programs have not been empirically evaluated nor was suicidal behavior a specific outcome measure.

There have been several empirical treatment trials for other psychiatric disorders relevant to suicidal youth (e.g., depressed, substance abusing, and conduct disordered youth). However, suicidal behavior has not been typically examined at follow-up. It is important for researchers conducting interventions in these areas to investigate the effects of the interventions on suicidal behavior. Another area of treatment research that may have relevance for the treatment of adolescent suicidal behavior is cognitive-behavioral treatment of Borderline Personality Disorder. Among suicide attempters, especially adults, self-injury is common. Conversely, individuals diagnosed with Borderline Personality Disorder very often display suicidal behavior. Thus, for adolescent suicide attempters who demonstrate repetitive suicidal behaviors, treatment approaches advocated for Borderline Personality Disorder may be useful. However, these interventions have yet to be tested with adolescent populations.

5.18.8.4 Primary Prevention of Suicidal Behavior

Suicide awareness programs have been advocated as a way to help adolescents become more sensitive to identifying a peer in suicidal crisis and helping the suicidal teen get the professional assistance that is needed. Thus, these programs may promote effective coping strategies in adolescents. Despite their intuitive appeal, the efficacy of these suicide prevention programs is, at best, modest. Shaffer et al. (1990) studied the effects of three different school-based prevention programs and found a significant increase in the proportion of students who admitted to personal difficulties, suicidal thoughts, or the need for professional help. A study of a 14-hour experiential program in Israel (Orbach & Bar-Joseph, 1992) reported a mild reduction of suicidal feelings and hopelessness. Girls seemed to benefit more than boys, and those students with greater suicidal tendencies improved more than their peers. Other studies suggest that knowledge may improve from such educational efforts, but that attitudes about suicide and behavior are largely unaffected immediately following the education (Shaffer et al., 1990; Spirito, Overholser, Ashworth, Morgan, & Benedict-Drew, 1988) and at 18-month follow-up (Vieland, Whittle, Garland, Hicks, & Shaffer, 1991). Kalafat and Elias (1994) did find a positive change in attitudes towards help-seeking and intervening with trusted peers. However, suicide awareness programs may be viewed most negatively by adolescents who have made a prior suicide attempt (Shaffer, Garland, Underwood, & Whittle, 1987). Another intervention program helped high-risk students but was no more effective than an assessment-only condition (Shaffer et al., 1987).

To be most helpful, specific programs targeting particular groups of adolescents (e.g., males vs. females, attempters vs. nonattempters, depressed vs. nondepressed) may need to be developed (Overholser, Hemstreet, Spirito, & Vyse, 1989). Alternatively, prevention programs that focus on general mental health interventions such as social skills training, problem solving, crisis management, and anger control may be more beneficial than programs focusing only on suicide (Berman & Jobes, 1991). Shaffer et al. (1988) reviewed the literature and found that only a minority of school-based programs were designed to improve teenagers' coping skills by training in stress management. For adolescents with no psychiatric disorders, the examination of maladaptive methods used when faced with difficult life situations and establishment of programs to improve problem-solving and coping skills may be helpful (Hawton, 1986).

5.18.9 PSYCHOPHARMACOLOGY

Psychotropic medication should be considered as a possible treatment modality for all adolescent suicidal behavior. At times, medication is clearly indicated for a particular psychiatric disorder such as major depression or bipolar affective disorder. At other times, medications may be helpful in reducing acute symptomology which, in turn, may improve the adolescent's acceptance and receptivity to other psychotherapies (Berman & Jobes, 1991). Of course, prescribing medications for suicidal adolescents requires careful monitoring, particularly for those adolescents thought to be at higher risk for reattempts. However, there have not been specific drug trials that have examined effects of medication on the functioning of suicide attempters.

5.18.10 EFFICACY/EFFECTIVENESS OF TREATMENTS

There have been several empirical treatment studies examining different therapy approaches with adult suicide attempters. Outpatient therapy and outreach following a suicide attempt have been found to result in fewer reattempts (Welu, 1977). Other studies have not found differences in reattempts after outreach programs (Gibbons, Butler, Urwin, & Gibbons, 1978). Lieberman and Eckman (1981) compared behavior therapy to insight-oriented psychotherapy in adult psychiatric inpatients following a suicide attempt. There was no difference in the reattempt rate between the two groups, although the behavior therapy group had significantly less suicide ideation and fewer suicide threats. In a 1990 study, cognitive-behavioral treatment was found to be slightly superior to standard care in reducing repeat attempts during a 6-month treatment course of adult suicide attempters (Salkovkis, Atha, & Storer, 1990). A similar treatment protocol found a reduction in hopelessness at follow-up, but no differences between groups that received a cognitive-behavioral treatment and nondirective treatment on suicidal ideation and intention at follow-up (Patsiokas & Clum, 1985).

There have been very few empirical trials of treatment with adolescent suicide attempters. Deykin, Hsieh, Joshi, and McNamara (1986) conducted randomized outreach intervention with adolescent suicide attempters after they had been seen in an emergency department. Social work follow-up with the families was offered to help the adolescents keep their follow-up appointments, to provide support, and explore additional services for the adolescents. The suicide attempters in the experimental group were twice as likely as controls to comply with recommendations for other services. In addition, they had fewer visits in the emergency department for suicidal behavior and follow-up. However, there was no difference in repeat suicide attempts after adjusting for prior history of suicidal behavior. The use of group therapy with adolescents with a history of suicidal behavior has also been described. Ross and Motto (1984) conducted a 35 session group over a 40-week period. The goals of the group treatment included providing a peer and professional support system, teaching ways to deal with stress and dysphoria, improving self-image, and teaching group members how to befriend others. At two-year follow-up, none of the 14 members of the group contacted had made further suicide attempts.

5.18.11 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

The significant international differences in adolescent suicide rates are not fully understood and need to be investigated further. Attempted suicide in adolescence is a much more frequent phenomena than completed suicide, but the epidemiologic knowledge base on attempted suicide is quite limited, both nationally and internationally. The World Health Organization is attempting to establish a more systematic data collection method regarding suicide attempts, and similar systems have been advocated by the Centers for Disease Control. Greater knowledge of the epidemiology of attempted suicide is important because it offers the potential to reach adolescents demonstrating suicidal behavior early in the spectrum of suicidality, and thus potentially having a greater effect on future lethal suicidal behavior.

The risk factors for completed suicide have been investigated fairly well. One area that deserves more attention is the influence of family and peers on adolescent suicidal behavior. A greater understanding in this area may lead to more primary prevention strategies and a subsequent reduction in suicide and suicidal behavior. As reviewed above, it is clear that the majority of adolescents who complete suicide have a diagnosable psychiatric disorder. The mental health field is in the early stages of its development of well-tested and effective treatment programs for the major psychiatric disorders related to adolescent suicidal behaviors, such as depression and substance use. Both psychosocial and psychopharmacologic treatments used for these psychiatric disorders are adopted from adult studies. As the mental health field advances and conducts more empirical research specifically looking at child and adolescent psychiatric disorders, the benefits of learning how to treat these disorders effectively will undoubtedly apply not only to the major symptoms of the disorder, but also to the associated symptoms such as suicidality.

Specific interventions designed to reduce adolescent suicidal behavior are few and far between. Although suicide attempters are a high-risk group in need of treatment, treatment proves particularly difficult with this population. Not only is treatment compliance a problem, but there is no such thing as standard psychotherapeutic care for a suicide attempter. This is probably due to the heterogeneous nature of the suicide attempters in this population. However, it would appear that future research should focus on testing at least some minimum guidelines for the treatment of suicide attempters in the months following a suicide attempt.

Secondary prevention of suicidal behavior is another area where clinical research is important. Intervention programs that might be tested in future research include services for populations at high risk for suicide, such as runaways, depressed adolescents, friends of adolescents who have completed suicide, and adolescents in families with a strong history of suicidal behavior. Primary prevention programs aimed at improving self-esteem and problem-solving skills in schools have the potential to improve mental health and possibly reduce the onset of suicidal behavior.

It is clear that approaches to both intervention and prevention of suicidal behavior among adolescents must incorporate a number of different perspectives. Such multi-pronged approaches will be necessary to advance clinical treatment and research in this area. Collaboration between researchers and clinicians in the field of adolescent suicidal behavior may improve our understanding of suicidal behavior and the interaction of environmental, psychological, and biological factors that need to be addressed in these adolescents.

5.18.12 SUMMARY

This chapter has provided an overview of the factors which contribute to both completed suicide in adolescence and/or attempted suicide in adolescence. Females attempt suicide much more frequently than males, while males complete suicide much more frequently than females. Caucasians attempt and complete suicide more often than members of other races. The most common psychiatric disorders implicated in suicide are depression, conduct disorder, and substance abuse. Comorbidity is often evident. Adolescents who have made a prior suicide attempt are at much greater risk for eventual completed suicide than those adolescents without a prior attempt. Use of a firearm in a suicide attempt greatly increases the risk of completing suicide. Prior exposure to suicidal behavior also increases the risk of suicidal behavior.

For adolescents who attempt suicide, a model for comprehensive assessment was presented. This model includes emotional (anger, depression, and hopelessness), cognitive (attributional style, problem solving, and perfectionism), and family factors. Treatments for suicidal behavior are in their infancy. Efficacy of the existing treatments has not been established. Interventions that focus on problem solving and affect management appear promising and in need of future research.

5.19.1 INTRODUCTION

The childhood disorder now known as attention-deficit hyperactivity disorder (ADHD) has a long and controversial history. A number of milestones are commonly cited in the evolution of the concept in its present form. The behavioral symptoms of inattention, impulsive behavior, and hyperactivity have remained fairly constant across many decades, although the interpretation of their origins and meaning has shifted with changes in the scientific paradigms of human behavior (Table 1).

At the end of the nineteenth century, mental afflictions were commonly divided into "moral" and physical causes. The attribution of moral carried different connotations from its usage today, meaning the impairment of judgment or restraint in the face of overwhelming stimulation, rather than mere unethical or immoral behavior. External and internal stimuli, including excesses of emotion and pain, were considered moral causes as opposed to purely physical causes. Because of their intensity they could overwhelm efforts to restrain impulse and thus prevent acting in acceptable ways. Thus, an influential text of the day stated that, "Every impression on the sensorium, through the external senses, and every passion in excess, may become a moral cause of insanity" (Burrows, 1828, p. 9).

Twenty years before Still (1902) provided his account of the impulsive, hyperactive child suffering from lapses in moral restraint, James provided a penetrating analysis of behavioral inhibition (James, 1890). Although his discussion of attention is deservedly well-known, few realize that James anticipated the modern linkage of attentional processes with behavioral inhibition and discharge of impulse into motor behavior. In adopting the traditional notion of a "moral" aspect of behavioral self-control, James argued that every overt action involves a hesitation requiring effortful attention to an "idea" that provides the impetus to action. A failure to restrain action is the consequence of a failure to hold the idea of a desired action in the focus of attention. This failure of attention is therefore the ultimate basis of an explosive and impulsive behavior pattern: "There is a normal type of character, for example, in which impulses seem to discharge so promptly into movements that inhibitions get no time to arise" (p. 537). Thus, James's influential opus established behavioral inhibition as exclusively a mental, as opposed to a physical, process—a process which linked impulsivity with inattention.

This was the prevailing paradigm when the physician Still (1902) provided an account of 20 youngsters whom he described as suffering from a defect of moral control. His clinical description of impulsive, inattentive, and overactive children anticipated much of what is now described as ADHD, although it also included features we would currently include under conduct, antisocial, or oppositional categories. These lapses in self-restraint did not discount the role of genetic and constitutional factors in the individual which might alter the threshold for succumbing to stimulation.

A shift of paradigms to a physical basis for behavioral disinhibition began three decades later. The catastrophic medical phenomena of the world wars, the pandemic of influenza and von Economo's encephalitis, along with the growing awareness of the long-term consequences of "reproductive casualties," provided the impetus to a more medical paradigm—specifically a neurological one—for explaining the deviant behavioral excesses and cognitive limitations of children. Although neuroanatomy was well-developed at this time, the neurological paradigms were largely those of a static system involving cortical inhibition over

Table 1 Some historical landmarks in the evolution of ADHD.

Author/event	*Contribution*
James (1890)	Linking of defects in voluntary inhibition of action to attentional phenomena: "Effort of attention is thus the essential phenomenon of will" (p. 562)
Still (1902)	Accurate clinical description of a syndrome of involving loss of "volitional inhibition" and "moral control"
Postencephalitis, in 1920	A syndrome described by numerous authors, involving emotional instability, irritability, lying, thieving, impaired memory and attention, poor motor control and general hyperactivity, and requiring milieu, cognitive, and behavioral therapies
Kahn and Cohen (1934)	Described the hyperkinetic syndrome as one of "organic-drivenness" due to brain-stem defects or (later) disinhibition due to cortical damage
Bradley (1937)	Administered benzedrine to a heterogeneous group of hospitalized hyperkinetic and behaviorally disordered children, noting an immediate calming effect on disinhibited behavior as well as an increased zest for learning
Goldstein (1942)	Based on observations of after effects of brain injuries in war, he called attention to many behavior patterns which were commonly considered "functional" as really being due to an "organic" etiology
Strauss and Lehtinen (1947)	Description of a brain damage syndrome with characteristic perceptual, motor, and emotional characteristics
Laufer, Denhoff, and Solomons (1957)	Comprehensive clinical description of a "hyperkinetic impulse disorder," with experiments implicating diencephalic (thalamic) mechanisms
Pasamanick and Knobloch (1959)	Described a "continuum of reproductive casualty" which was responsible for a syndrome of minimal cerebral damage in infancy
Clements and Peters (1962)	A classic paper describing the concept of minimal brain dysfunction, later formalized by Clements (1966) in a consensus statement, and linked to attentional dysfunctions by others from the Arkansas group (Dykman, Ackerman, Clements, & Peters, 1971)
American Psychiatric Association (1980)	Formalization of a diagnostic category whose core disorder is attentional in nature, and in which separate subtypes are evident involving hyperactivity, impulsivity, and inattention

more primitive appetitive systems. Organic explanations of behavior were largely based on a conception of the brain along strict localization of functions within separate structures. But Goldstein's (1942) studies of penetrating head wounds and war injuries broadened the range of behavioral phenomena from localized motor impairments to subtle disturbances of cognitive function such as "concrete thinking." These early postwar writings provided a way of understanding subtle behavioral disturbances as organically based phenomena linked to specific types of brain damage. "Organicity" came to mean a style of behavior as much as a statement of etiology.

During this same period, a very different paradigm was provided by Gestalt psychology, with its focus on the role of perceptual phenomena such as visual illusions. Here the emphasis was on the way the brain organizes sensory input and regulates output according to certain principles involving goodness of fit and whole–part relationships among sensory elements. Motor acts reflected control by organized perceptual structures. Werner, Strauss, and their colleagues applied these paradigms to the plentiful cases of children with identifiable neurological conditions such as cerebral palsy, providing an impetus to the perceptual-motor re-education programs initiated by Cruikshank and others in the early and mid-1940s (Kessler (1980) gives a good account of this period).

These studies of relatively extreme medical phenomena gradually filtered into thinking about behaviors that were not readily explained by obvious neurological antecedents. Eventually, however, it became clear that the paradigm of neurological damage had to be abandoned because many cases of apparently organic behavior had no identifiable neurological insults. But the notion lingered on that the perceptual, motor, and learning features associated with known brain damage were indicators of underlying brain dysfunction, but dysfunction that was minimal compared to the usual neurological catastrophes. The concept of minimal brain dysfunction (MBD) was the immediate progenitor of current descriptive classifications of the disruptive behavior disorders, including ADHD. In the definitive conference paper describing the syndrome of MBD, Clements (1966) proposed that:

> The term "minimal brain dysfunction syndrome" refers ... to children of near average, average, or above average intelligence with certain learning or behavioral disabilities ranging from mild to severe which are associated with deviations of function of the central nervous system. [The disabilities may be shown by] various combinations of impairment in perception, conceptualization, language, memory and *control of attention, impulse, or motor function* [italics added]. (pp. 9–10)

This concept incorporates much of the language and thinking of the previous 70 years, in which learning and behavioral disabilities were linked to the central nervous system through characteristic perceptual, cognitive, and motor patterns, and highlights the role of control of attention, impulse and motor function.

It is generally believed that the term MBD was eventually replaced for lack of direct evidence regarding brain dysfunction (Barkley, 1996). In fact, the concept received considerable support. The prospective perinatal collaborative study by the National Institute of Neurological Diseases and Blindness of 56 000 children followed from birth, demonstrated that symptoms of overactivity and learning disabilities were clearly predictable from adverse perinatal events, including maternal smoking and alcohol use (Nichols & Chen, 1981). As fundamental neuroscience has advanced, there has been unexpected further support for the concept of MBD. As noted by Rapoport and Castellanos (1996), "Since the publication of *DSM-III-R* in 1987 ... a number of anatomic MRI studies ... have in fact documented minimal but significant brain anatomical deviations—ironically, minimal brain dysfunction now takes on new meaning!" (p. 267).

However, the boundaries of the MBD concept were simply too large, allowing as it did for various combinations of impairment across many types of behavior. Anticipating the integrative review by Douglas and Peters (1978), the Arkansas group (Clements & Peters, 1962; Dykman, Ackerman, Clements, & Peters, 1971) began to narrow the core processes to attention. At the same time, the second edition of the *Diagnostic and statistical manual of mental disorders* (*DSM-II*) defined the hyperkinetic reaction of childhood as a disorder "characterized by overactivity, restlessness, distractibility, and short attention span." (American Psychiatric Association, 1968, p. 50.) This definition is etiological in that it characterizes the syndrome as a reaction, in keeping with then-prevailing psychoanalytic doctrine. Between the introduction in 1980 of *DSM-III* and of *DSM-IV* in 1994, opinion vacillated regarding the centrality of attention and hyperactivity/impulsivity in the syndrome, but etiological explanations were no longer included as necessary in a system which attempts to be purely descriptive.

This brief review highlights the evolutionary nature of the ADHD concept, and its dependence upon the prevailing scientific paradigms used to explain behavior and mental functioning. Evolution of the concept has proceeded from the mentalistic formulations of the nineteenth century, to the organic concepts of the early twentieth century, and finally to a purely behavioral and descriptive formulation. This chapter depicts the current state of the art with respect to assessment, diagnosis, and treatment, and points to the clinical and research goals which are yet to be achieved in understanding the disorder and its treatment.

5.19.2 PHENOMENOLOGY

5.19.2.1 Core Features

Despite great variation with respect to diagnostic labels, etiologic theories, and conceptions of primary deficits, clinical descriptions of children with the neurobehavioral syndrome now referred to as ADHD have been remarkably stable. The doggerel verse used to describe *Fidgety Phil* in 1863 by the German pediatrician Heinrich Hoffman might today be replaced by a downloaded video clip of a hyperactive child, but the symptoms depicted by any medium will include some combination of developmentally inappropriate levels of inattention, impulsivity, and overactivity that emerge early in life and persist with time and across situations. Indeed, despite comprising a heterogeneous set of behavioral and cognitive problems, it has been parsimonious to consider the symptoms of ADHD as emerging from deficient regulation in three areas: attention, response inhibition, and activity level. This familiar tripartite division of core features has not always been supported by factor analytic studies of parent and teacher behavior ratings, from which two rather than three stable dimensions consistently emerge (Hinshaw, 1994). One factor comprises inattention, cognitive impulsivity and, in some instances, restlessness, whereas the other is formed by behavioral impulsivity and motoric overactivity (Bauermeister, Alegria, Bird, Rubio-Stipec, & Canino, 1992; Lahey et al., 1988). However, in a study of a national normative sample, confirmatory factor analysis was used to demonstrate that a three-factor model was the best fit to the 18 *DSM-IV* symptoms (Conners, Parker, & Sitarenios, 1996). Nevertheless, the high correlation of the impulsivity and hyperactivity factors justifies their lumping together for practical purposes. Hence, the current diagnostic system employed in the USA (discussed below) defines inattention and hyperactivity–impulsivity as the core broad dimensions of ADHD.

It has long been recognized that the core features of ADHD, however partitioned, do not represent unitary constructs and precise specification of symptoms is lacking. The following are brief discussions of the heterogeneity and phenomenology of these features.

5.19.2.1.1 Inattention

Although coordinated in function, multiple dimensions of attention have been identified and evidence is emerging that each type reflects a separate underlying neural network (Mesulam, 1990; Posner, 1988; Voeller, 1991 (review)). Components of attention most consistently described include (i) arousal or alertness, (ii) selective or focused attention (the ability to attend to particular stimuli while ignoring competing, irrelevant stimuli), (iii) attentional capacity or span of apprehension (the amount of information to which the child can attend at one time), and (iv) sustained attention or vigilance (the persistence of focus over time). Clinically, children with ADHD may show fairly specific attentional problems, but more often have attentional difficulties that are multifaceted. Common manifestations include an inability to remain engaged in schoolwork, chores (and, in some instances, games), high rates of off-task behavior, seeming to be in another world when being spoken to, difficulties recalling and following through on instructions with multiple steps, poor task completion, distractibility by stimuli that are more appealing than the task at hand, and a disregard for details that often leads to careless mistakes.

Laboratory evidence compiled by Douglas in the 1980s (Douglas, 1983) led to the predominant view that poor sustained attention or vigilance represented the core deficit in children with ADHD. Indeed, the frequency with which these children drift off-task and fail to persist with effortful activities of low inherent interest suggests a vigilance decrement. However, results of laboratory studies aimed at illuminating this attention deficit have been conflicting. Whereas some investigations reveal deficient vigilance in ADHD samples (e.g., Seidel & Joschko, 1990), many have failed to support a sustained attention deficit (e.g., Schachar, Logan, Wachsmuth, & Chajczyk, 1988; Sergeant & Scholten, 1985; van der Meere, Wekking, & Sergeant, 1991). Part of the problem is that the vigilance decrement is an age-related phenomenon which is much less evident in older children and adolescents (Seidel & Joschko, 1990). In light of such findings, some have argued that the clinical phenomena commonly interpreted as a sustained attention deficit actually reflect a problem with the preparation, regulation, speed, and consistent execution of motor output (Barkley, 1995b; van der Meere, van Baal, & Sergeant, 1989). Barkley (1994) has reframed attentional problems in children with ADHD as deficits in goal-directed persistence, meaning that the persistence of their effortful behavior is highly dependent on the nature of the task context (e.g., intrinsic interest or novelty) and on immediately available reinforcement rather than being shaped by distal rewards and future goals. Clearly, the nature and primacy of attentional problems in ADHD remain elusive. Contributing to this state of affairs is the complex intertwining of cognitive, motivational, affective, and behavioral variables, along with varying task parameters, in the responses regarded as reflecting attention, both in the laboratory and the natural environment.

5.19.2.1.2 Hyperactivity

Characteristic symptoms in the hyperactive domain vary in both nature and degree. Features ranging from excessive talking and noise-making, to an inability to remain seated, are regarded as reflecting hyperactivity. The category encompasses both the child who taps his feet, fidgets, and manipulates objects when seated, to the whirling dervish who blazes chaotically through space with a driven, accelerated quality. Common to many of the symptoms in this domain is that they lack direction or purpose and are extraneous to the task at hand. As with inattentive symptoms, there is significant situational variability in hyperactivity (Luk, 1985), suggesting a deficient capacity to regulate activity levels to different setting or task demands (Routh, 1978). Thus, the child who stands out so painfully in the structured classroom setting may be far less distinguishable from peers on the playground. Despite the modulation of hyperactive symptoms by environmental factors, it is noteworthy that youngsters with ADHD generally exhibit greater levels of motor activity than comparison children throughout the day, including during sleep (Porrino et al., 1983). Moreover, whereas certain measures of inattention have not been found to distinguish children with ADHD from those with other psychiatric conditions, hyperactivity may represent a more specific marker of the disorder (Halperin, Matier, Bedi, Sharma, & Newcorn, 1992; Roberts, 1990).

5.19.2.1.3 Impulsivity

Although current *DSM* criteria in the impulsivity domain are limited to blurting out answers prematurely, difficulty waiting one's turn, and interrupting or intruding upon others, other impulsive features are commonly observed in children with ADHD, including engaging in physically dangerous activities without considering the possible consequences, deficient inhibition of intense emotional responses, and a hasty, careless response style when working on tedious or cognitively demanding tasks (Brown & Quay, 1977). A proclivity towards impulsive acts may also underlie the higher than average accident rate seen among youngsters with ADHD (Hartsough & Lambert, 1985; Szatmari, Offord, & Boyle, 1989a).

As with inattention and hyperactivity, the category of impulsivity is often conceptualized in an overly inclusive manner which makes it difficult to operationalize. Convergent validity is problematic as various measures of impulsivity (e.g., continuous performance tests, matching familiar figure tests, and parent or teacher ratings) tend to correlate poorly with one another (Milich & Kramer, 1984). There does, however, appear to be justification for distinguishing cognitive and behavioral aspects of impulsivity as they appear to be distinct factors (Taylor, 1994), with differing diagnostic and predictive significance. For example, measures of cognitive impulsivity have been found to distinguish ADHD from psychiatric comparison children (Halperin et al., 1992). In a longitudinal study of 400 boys conducted by White et al. (1994), both cognitive and behavioral impulsivity predicted academic achievement problems, but only the latter was associated with increased risk for antisocial behavior.

In contrast to prior conceptualizations of the disorder that identified hyperactivity or inattention as primary deficits, Barkley (1994) has argued that an impaired capacity to inhibit or delay responding is at the core of ADHD. This theory contends that the chief and associated features of ADHD can be regarded as secondary to poor inhibitory control. For instance, the capacity to inhibit responses is said to permit self-regulation which, in turn, limits task-irrelevant motor activity and makes persistence in the face of boredom, fatigue, or competing stimuli possible. Thus, Barkley reverses the causal direction of the relationship between impulsivity and inattention as interpreted by James.

5.19.2.2 Associated Features and Comorbidity

The phenotypic heterogeneity of ADHD is a product not only of the variegated nature of its core symptoms, but also multiple associated clinical features and co-occurring psychiatric conditions. The most common secondary features among children with ADHD include academic underachievement, noncompliant and aggressive behavior, family discord, and poor peer relationships. Adequate functioning in these domains has significance for mastering many critical developmental tasks (Richters et al., 1995). Conversely, poor functioning in these areas is highly predictive of later maladjustment (Hinshaw, 1994), making these secondary features of ADHD particularly pernicious. The following are brief comments regarding the particular difficulties experienced in these domains by children with ADHD.

The symptoms of ADHD typically compromise a child's ability to meet academic as well as behavioral demands at school. An overwhelming majority of children with the disorder demonstrate academic performance problems relative to their classmates (Cantwell & Baker, 1991), as indexed by lower rates of on-task behavior (Abikoff, Gittelman-Klein, & Klein, 1977) and academic task completion (Pfiffner & Barkley, 1990), and by higher rates of academic underachievement, placement in special education services, grade retention, and dropping out of school (Barkley, DuPaul, & McMurray, 1990; Barkley, Fischer, Edelbrock, & Smallish, 1990; Hinshaw, 1992b). Learning disabilities are highly correlated with externalizing or disruptive behavior disorders in general, but the relationship appears to be strongest with ADHD (DuPaul & Stoner, 1994; Hinshaw, 1992b). Although prevalence estimates of learning disorders among youngsters with ADHD vary widely, most recent estimates employing conservative criteria for defining learning disorders range from 10% to 25% (Hinshaw, 1992a; Semrud-Clikeman et al., 1992). Despite their far above chance co-occurrence and complex bidirectional influences, consensus has emerged that ADHD and learning disabilities represent distinct disorders (Shaywitz, Fletcher, & Shaywitz, 1995).

Children with ADHD commonly manifest a variety of externalizing features. These typically involve willful noncompliance or defiance in response to adult directives or rules, disruption of ongoing activities, argumentativeness, temper outbursts, verbal hostility, and physical aggression (Loney & Milich, 1982). Such behaviors are often of sufficient severity and duration to warrant a diagnosis of oppositional defiant disorder (ODD), which pertains to recurrent, age-inappropriate patterns of negative, defiant, and hostile behaviors, often accompanied by an irritable mood (American Psychiatric Association, 1994). Recurrent patterns of the more serious antisocial behaviors (e.g., stealing, property destruction, aggression towards persons or animals, deceit, truancy) that comprise conduct disorder (CD) (American Psychiatric Association, 1994) are less common than ODD features but still co-occur with ADHD at rates that far exceed chance. The rates of ODD or CD found in ADHD samples have ranged from 30% to over 50% (Anderson, Williams, McGee, & Silva, 1987; Beiderman, Newcorn, & Sprich, 1991). Despite the high degree of overlap between ADHD and both ODD and CD, research, examining group differences in variables including environmental background, family psychiatric history, cognitive impairments, family interactions, and course, supports the partial independence of these syndromes (Abikoff & Klein, 1992; Hinshaw, 1987). Moreover, those ADHD children with comorbid CD may represent a qualitatively distinct subgroup from ADHD youngsters without a comorbid disruptive behavior disorder (Hinshaw, 1994).

The intra- and extrafamilial interpersonal functioning of ADHD children is frequently disturbed. Elevated rates of negative and conflictual parent–child interactions characterize families with an ADHD child (Barkley, Karlsson, & Pollard, 1985; Mash & Johnston, 1982). In addition, these families are marked by higher levels of parental stress and psychopathology and lower levels of marital harmony and self-perceived parenting competence than those found in families without a disturbed child, although some of these findings apply to ADHD children with comorbid ODD or CD (Anastopoulos, Guevremont, Sheton, & DuPaul, 1992; Anderson, Hinshaw, & Simmel, 1994; Johnston, 1996; Schachar & Wachsmuth, 1990). The interactions of ADHD children with their teachers, like those with parents, are often characterized by lower than average rates of positive exchanges and higher rates of commands and negativity (Pfiffner & Barkley, 1990). Although the child and parent characteristics are bidirectional in their effects, it is worth emphasizing that many negative parent characteristics disappear with corrective intervention with the child, an important therapeutic point in reducing the guilt of parents prone to blame themselves for the appearance of the child's behavioral symptoms.

Peer relationships are also typically disrupted as children with ADHD have difficulties initiating and maintaining friendships (Guevremont, 1990). In fact, studies employing sociometric measures with ADHD samples have consistently revealed them to be poorly accepted or actively rejected by peers at much higher rates than normal children and children with other psychiatric disorders (Asarnow, 1988; Milich & Landau, 1982; Whalen & Henker, 1992). Rather than arising from deficient prosocial skill deficits, the social failure experienced by ADHD children appears to relate most strongly to their interpersonally noxious behaviors (e.g., aggression, noncompliance, disruption, and intrusiveness), affective dysregulation, and impaired capacity to modulate their social responses to shifting environmental demands. Moreover, the peer rejection suffered by children with ADHD emerges after very brief periods of interaction (Erhardt & Hinshaw, 1994; Pelham & Bender, 1982), is stable over time, and represents a robust predictor of a variety of adverse long-term outcomes (e.g., academic failure, school dropout, criminality or psychopathology) (Parker & Asher, 1987).

With respect to formal psychiatric diagnoses, ADHD is most commonly comorbid with ODD, CD, and learning disorders (see previous discussion). However, other disorders also co-occur with ADHD at above-chance levels. Indeed, it is more common for ADHD to present with one or more comorbid conditions than in the absence of another diagnosis (Newcorn & Halperin, 1994). These include anxiety disorders, which may occur in 25% or more of children with ADHD (Biederman et al., 1991), expressive language disorders (Hamlett, Pelligrini, & Conners, 1987; Zentall, 1989), Tourette's and other tic disorders (Cohen & Leckman, 1994), and motor coordination deficits (Barkley, 1990). The evidence with respect to co-occurring mood disorders is mixed, with some studies finding substantially elevated prevalence rates (Biederman, et al., 1991) and others reporting no significantly enhanced risk for affective illness in ADHD samples (Gittleman, Mannuzza, Shenker, & Bonagura, 1985; Lahey et al., 1988). Consideration of comorbid conditions is critical as they may have important implications for etiology, severity, course, and response to both pharmacologic and psychosocial treatments (March, Wells, & Conners, 1995a; Newcorn & Halperin, 1994).

5.19.2.3 Variations Related to Gender and Development

5.19.2.3.1 Gender

The expression, associated features, and course of ADHD in females is receiving increasing attention. However, research in this area remains scarce and what exists is plagued by small sample sizes which limit statistical power and preclude definitive conclusions regarding gender differences. The following comments on what is currently known have been culled from Arnold's (1996) summary of the findings emerging from a conference convened in late 1994 by the Child and Adolescent Disorders Branch of the National Institute of Mental Health to review the literature on gender differences in ADHD.

A preponderance of available evidence suggests a basic similarity between males and females with respect to the qualitative expression of the disorder; quantitatively, however, females with ADHD may, on average, show less hyperactive–impulsive behavior and less inattention than do their male counterparts. It is important to bear in mind that similar gender differences with respect to these behaviors exist in the normal population (Achenbach & Edelbrock, 1983; Goyette, Conners, & Ulrich, 1978), which raises the thorny issue of whether gender-based norms for establishing deviance should be incorporated into diagnostic thresholds. Diagnostically, the Predominantly Inattentive subtype of ADHD appears to be overrepresented in females compared to the Combined subtype (Lahey et al., 1994). Gender differences have emerged for comorbid conditions, as males with ADHD exhibit a higher rate of antisocial-spectrum difficulties, including aggression, oppositional-defiant behavior, and conduct disorder symptoms. Although some data suggest more severe intellectual, learning, and language deficits in females with ADHD, findings related to these variables are few and sufficiently mixed that conclusions would be premature. Sex-based differences in response to psychostimulant medications do not appear to exist. Insufficient evidence exists to address whether the outcomes of males and females with ADHD differ, although the greater severity of core symptoms and higher levels of associated antisocial problems may presage a more negative outcome for males. Concerns continue to be raised that females with ADHD represent an underdiagnosed and underserved population.

5.19.2.3.2 Developmental variation

The diagnosis of ADHD and the delineation of a coherent clinical picture of the disorder across the life-span are complicated by the developmental nature of the constituent behaviors. Many preschool-aged children are highly active and exhibit both inattentive and impulsive behaviors. Yet it is often difficult to distinguish normal variation in such behaviors that will dissipate as development proceeds, from the initial expression of a pathological syndrome that is likely to be chronic, impairing, and deserving of treatment (Campbell, 1990). Nevertheless, early onset behavior problems prove to be chronic and serious in a proportion of children who show such difficulties, particularly when a constellation of overactive, inattentive, impulsive, and defiant behaviors are fairly severe, persist for a year or longer, and are accompanied by negative parenting practices and family adversity (Campbell, 1990, 1995; Richman, Stevenson, & Graham, 1982). As discussed later in this chapter, it is now well-established that symptom patterns of sufficient severity and duration to warrant a diagnosis of ADHD in early childhood tend to persist at least into adolescence in a substantial majority of cases (Weiss & Hechtman, 1993).

Another way in which ADHD represents a developmental disorder is that its expression typically varies with age. Despite a trend toward overall symptom reduction with maturity (Barkley, 1990), both core and associated symptoms tend to be present in each age group, but with an altered topography. March et al. (1995a) summarize how ADHD symptoms manifest at different ages; Weiss & Hecthman (1993) provide a detailed discussion. For example, hyperactivity declines with age and minor extraneous motor behaviors (e.g., fidgeting or tapping) or an internal sense of restlessness may replace the excessive running and climbing of early and middle childhood (American Psychiatric Association, 1994). Some researchers have failed to find similar developmental declines in inattentive symptoms (Hart, Lahey, Loeber, Applegate, & Frick, 1995; Parker, Sitarenios, & Conners, 1996). Changes in symptom patterns are likely to reflect not only physiological maturation but also shifting social ecologies and environmental demands (Whalen & Henker, 1980). During adolescence, increased demands to manage multiple classes, to complete multistaged projects within a certain time-frame, and to structure one's own time, tend to increase the salience of organizational and executive functioning deficits in ADHD (Wender, 1995). Conversely, many symptoms may become less notable once individuals escape the unique demands of school and exercise greater freedom to determine working and living environments which provide a better match for their particular profile of strengths and deficits.

5.19.3 DIAGNOSIS

As part of the comprehensive assessment process described later in this chapter, the clinician will typically determine whether a child satisfies official diagnostic criteria for ADHD. Although limited in scope and utility, arriving at an accurate categorical diagnosis does represent a legitimate part of the assessment process as it serves a number of important functions. These include providing a common language for communication among professionals for both research and clinical purposes, conveying useful information on likely associated features, course, and treatment response and, on a more pragmatic level, facilitating the payment for clinical services by insurers and managed care providers (Volkmar, 1991).

The evolution of diagnostic systems for ADHD has been both incited and accompanied by constant debate regarding definitional boundaries, labels, and primary symptoms. The frequent changes in classification schemes and marked differences between those used in the USA and Europe have obstructed progress in our understanding of the disorder because they have compromised the legitimacy of cross-study comparisons. As noted by Hinshaw (1994), the ultimate aim of any categorical diagnostic scheme is to identify subgroups of individuals who are homogeneous with respect to presentation, pathogenesis, family history, course, and treatment response. Although this still represents a distal goal with respect to psychiatric nosology, progress is evident in the increasing reliance on empirical field trials of prospective criteria along with expert consultation to inform diagnostic systems (Lahey et al., 1994).

One by-product of such progress is the growing rapprochement between the two major taxonomies for psychopathology: the *DSM-IV* in the USA (American Psychiatric Association, 1994) and the *International statistical classification of diseases and related health problems, tenth revision* (*ICD-10*) (World Health Organization, 1992a). Conceptually, these diagnostic systems are quite similar in that the behavioral symptoms each lists as comprising ADHD are identical or show only minor variations in wording. The *DSM-IV* criteria for ADHD are listed in Table 2.

In addition to their overlap in symptom content, both criteria sets stipulate that symptoms be present to developmentally inappropriate degrees, persistent for at least six months, pervasive across settings, emergent before (*DSM-IV*) or by (*ICD-10*) the age of seven, and associated with significant impairment in social, academic, or occupational functioning (although significant distress can substitute for impairment in *ICD-10*). Despite their gradual convergence, significant differences remain between the diagnostic approaches to ADHD contained in *DSM-IV* and *ICD-10*. The *DSM-IV* system, drawing upon the results of factor analytic studies and extensive field trials (e.g., Bauermeister et al., 1992; Lahey et al., 1984, 1988), groups symptoms into the two dimensions of inattention and hyperactivity–impulsivity and defines three diagnostic subtypes on the basis of an individual's profile on these dimensions. Specifically, "ADHD Combined Type" requires at least six of the nine symptoms in both the inattention and hyperactive–impulsive domains, whereas the "ADHD, Predominantly Inattentive Type" and the "ADHD, Predominantly Hyperactive–impulsive Type" each require six or more symptoms in one problem area but fewer than six symptoms in the other domain.

The distinction of an inattentive subtype of ADHD (which is also commonly referred to as "attention deficit disorder without hyperactivity") is well supported by factor and cluster analytic studies and by data showing that family history and comorbid symptom patterns in such a subgroup diverge from those found in other children who are diagnosed with ADHD (Cantwell & Baker, 1992; Goodyear & Hynd, 1992). However, the validity of the unprecedented predominantly hyperactive–impulsive subgroup is less well established. This subtype has been found to apply disproportionately to children below school age (Lahey et al., 1994) who have had little opportunity to exhibit inattentive symptoms which become most evident in demanding, structured environments (e.g., careless errors, disorganization, or poor task completion). Thus, some suggest that the predominantly hyperactive–impulsive group may represent a developmental precursor of "ADHD, combined type" rather than a distinct subtype (Barkley, 1995a). Nonetheless, the *DSM-IV* criteria for ADHD is generally regarded to be an improvement over its predecessors, yielding diagnoses that are more reliable and more clearly associated with functional impairment (McBurnett, Lahey, & Pfiffner, 1993).

In *ICD-10*, the term "hyperkinetic disorder" is adopted rather than ADHD, and inattention, hyperactivity, and impulsivity are listed as separate problem areas, with diagnosis requiring symptoms in all three domains. However, inattention and hyperactivity are regarded as cardinal features and are emphasized over impulsive symptoms (World Health Organization, 1992b). Thus, the diagnosis of "hyperkinetic disorder" requires the presence of six of

Table 2 *DSM-IV* diagnostic criteria for attention-deficit hyperactivity disorder.

A. Either (1) or (2):

(1) Six (or more) of the following symptoms of **inattention** have persisted for at least six months to a degree that is maladaptive and inconsistent with development level:

Inattention

- (a) often fails to give close attention to details or makes careless mistakes in schoolwork, work, or other activities
- (b) often has difficulty sustaining attention in tasks or play activities
- (c) often does not seem to listen when spoken to directly
- (d) often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions)
- (e) often has difficulty organizing tasks and activities
- (f) often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as schoolwork or homework)
- (g) often loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, or tools)
- (h) is often easily distracted by extraneous stimuli
- (i) is often forgetful in daily activities

(2) Six (or more) of the following symptoms of **hyperactivity–impulsivity** have persisted for at least six months to a degree that is maladaptive and inconsistent with developmental level:

Hyperactivity

- (a) often fidgets with hands or feet or squirms in seat
- (b) often leaves seat in classroom or in other situations in which remaining seated is expected
- (c) often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
- (d) often has difficulty playing or engaging in leisure activities quietly
- (e) is often on the go or often acts as if driven by a motor
- (f) often talks excessively

Impulsivity

- (g) often blurts out answers before questions have been completed
- (h) often has difficulty awaiting turn
- (i) often interrupts or intrudes on others (e.g., butts into conversations or games)

B. Some hyperactive–impulsive or inattentive symptoms that cause impairment were present before age seven years

C. Some impairment from the symptoms is present in two or more settings (e.g., at school/work and at home)

D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning

E. The symptoms do not occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or other psychotic disorder and are not better accounted for by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, or a personality disorder)

Code based on type:

314.01 Attention-Deficit Hyperactivity Disorder, Combined Type: if both criteria A1 and A2 are met for the past six months

314.00 Attention-Deficit Hyperactivity Disorder, Predominantly Inattentive Type: if criterion A1 is met but criterion A2 is not met for the past six months

314.01 Attention-Deficit Hyperactivity Disorder, Predominantly Hyperactive–Impulsive Type: if criterion A2 is met but criterion A1 is not met for the past six months

Diagnostic and statistical manual of mental disorders (4th ed.), American Psychiatric Association, 1994, Washington, DC: Author. Copyright 1994 by American Psychiatric Association. Reprinted with permission.

nine symptoms of inattention, three of five hyperactive features, and one of four impulsivity symptoms. Of note is the fact that the item pertaining to excessive talking, which is grouped with the hyperactivity features in *DSM-IV*, is placed among the impulsivity items in *ICD-10*.

Other differences between the *DSM-IV*, and *ICD-10* systems pertain to subtyping, exclusionary criteria, and comorbidity. For example, *ICD-10* regards the predominantly inattentive and predominantly hyperactive–impulsive subtypes of ADHD, recognized by *DSM-IV*, to be subthreshold conditions for which separate diagnostic codes are not provided. Rather, the primary division within the *ICD-10* hyperkinetic disorders is between "disturbance of activity and attention," which corresponds closely to the *DSM-IV* ADHD, combined type, and "hyperkinetic conduct disorder," a mixed category that is applied when the criteria for both hyperkinetic disorder and conduct disorder are met.

The existence of the hyperkinetic conduct disorder diagnosis in *ICD-10* illustrates one difference in the way in which the two nosologies manage the comorbidity so common to ADHD. As discussed by Taylor (1994), *DSM-IV* represents a multiple diagnosis scheme in which comorbid diagnoses are readily assigned if the criteria for each is met, provided that the symptoms of one disorder are not better accounted for by a coexisting condition. Contrasting with this approach is the single diagnosis scheme adopted by *ICD-10*. Although multiple diagnoses are permitted, the system steers the diagnostician towards choosing a single disorder on the basis of the best available match between the child's presentation and the prototypic descriptions offered in *ICD-10*. Supporting this more conservative approach to multiple diagnoses is the inclusion in *ICD-10* of precedence rules (e.g., depressive and anxiety disorders generally take precedence over hyperkinetic disorders) and listing of exclusionary criteria which are more restrictive than those found in *DSM-IV*. One limitation common to both classification schemes is the developmental insensitivity of both the symptoms listed and the diagnostic thresholds (Barkley, 1995a; Hinshaw, 1994). Thus, preschool children and adults are judged by the same items and diagnosed using the same cutpoints, despite the changing topography and severity of symptoms with maturation. Taylor (1994) provides a more detailed consideration of the *DSM* vs. *ICD* approach to diagnosing ADHD.

Regardless of which classification scheme is used, a number of additional factors complicate the clinical judgment involved in assigning an ADHD diagnosis and create the potential for both overdiagnosis and misclassification. First, many of the symptoms occur frequently in nondisordered youngsters and reflect normal developmental variation rather than an underlying pathology. Second, the heterogeneous presentation of ADHD children and the variability in performance and symptom expression within a given child as a function of time, task, and setting variables can make the disorder an elusive target. Third, many of the symptoms are not specific to ADHD but can be associated with other forms of psychopathology (e.g., anxious or depressive disorders) and with adverse environmental circumstances (e.g., chaotic families, ineffectual classrooms, or psychosocial stressors). These potential pitfalls in diagnosing ADHD place a premium on the clinician's assessment of the developmentally deviant and impairing nature of presenting symptoms, reliance on a comprehensive multimodal, cross-informant assessment battery, and command of child psychopathology to aid in differential diagnosis.

Detailed differential diagnosis is especially important in ADHD due to both the frequent co-occurrence of ADHD with other disorders (as discussed above) and to the potential for other syndromes to produce symptoms that overlap with the behavioral criteria for ADHD. Examples of the potential clinical implications of differential diagnosis include the markedly different patterns of impairment and outcomes that typify ADHD with and without conduct disorder (Hinshaw, 1992a; Walker, Lahey, Hynd, & Frame, 1987), the divergent treatment plans indicated for ADHD, learning disorders, and their combination (DuPaul & Stoner, 1994), and the less favorable stimulant response among ADHD children with comorbid anxious disorders (Pliszka, 1989). Although a detailed discussion of differential diagnosis in ADHD is beyond the scope of this chapter (see Barkley, 1990; Sharma, Matier, & Halperin, 1994), the process typically requires a thorough knowledge of the full spectrum of childhood disorders and reference factors such as age and type (acute versus insidious) of onset, course (episodic versus chronic), symptom pervasiveness, family psychiatric history, and the child's environmental context (e.g., psychosocial stressors, family relations, and school climate).

5.19.4 PREVALENCE

The reported prevalence of any disorder is strongly affected by many variables, including the definition of "caseness," sampling methods, the sampling frame, age, and comorbidity. These factors probably account for the range of prevalence of 2–6.3% in recent studies of

ADHD (Szatmari, Offord, & Boyle, 1989b), and 20% or more in some older studies.

5.19.4.1 Caseness Criteria

Slight differences in symptom criteria can markedly affect recorded prevalence of the disorder. When the *DSM* shifted from the hyperactivity–impulsivity–inattention criteria of *DSM-III* to the single list of 14 symptoms of *DSM-III-R*, ADHD became 14.4% more prevalent than attention deficit disorder/hyperactivity (Lahey, Loeber, Stouthamer, Christ, 1990). It had been observed for some time that English clinicians tended to record far fewer cases of their *ICD-9* equivalent of attention deficit disorder (ADD) (hyperkinetic disorder), than their American counterparts. The causes of this unequal prevalence of hyperactivity in the UK and the USA were investigated by British and American clinicians and research panels using both *ICD-9* and *DSM-III* criteria. Although there was poor clinician reliability, the specially trained research panels reliably found that *ICD-9* generated fewer diagnoses of hyperkinetic syndrome than did *DSM-III* for attention deficit disorder with hyperactivity. This difference was greatest for UK clinicians, and both the diagnostic scheme and clinician training contributed significant variance to the difference in reported rates (Prendergast et al., 1988). When using standard rating scales, the mean hyperactivity score of English schoolchildren is actually higher than their American peers (Taylor & Sandberg, 1984).

Questionnaires can yield any prevalence rate, depending upon the choice of cutoff score. But other factors affect prevalence obtained by ratings. The format of questionnaires used for assessing hyperactivity or ADHD can have an impact on the obtained prevalence rates. In a study of 2000 Australian and English schoolchildren, a rate of 5.6% was found using the Conners teacher rating scale, 7.5% using a scale which compared behavior to a normal standard, and 8.9% using a scale with yes–no format. When all three scales were required for inclusion, the rate dropped to 3.5%, whereas the rate for identification by any one of the three scales rose to 12% (Holborrow, Berry, & Elkins, 1984).

The symptom informant has a strong effect on recorded prevalence. One of the largest studies, carried out on 5000 children in the Bay area of San Francisco, demonstrated that hyperactivity varied from 1% to 12% depending upon whether one, two, or three "system definers" of parent, teacher, and clinician made the diagnosis (Lambert, Sandoval, & Sassone, 1978). One study, using a structured diagnostic interview with mid-Western nine-year-olds and a parent, found a rate of 3.5% by child report, 12% by parent report, and 1.7% when both were required (Shekim et al., 1985).

5.19.4.2 National and Cultural Factors

In identifying the setting and task parameters which affect the expression of ADHD symptoms, researchers have been sensitive to context in a narrow sense. However, less attention has been paid to the impact of broader contextual issues such as culture, socioeconomic status, and ethnicity, on the expression, course, treatment response, and outcome of ADHD. The behavioral features that comprise ADHD appear in diverse cultures, although reported prevalence rates vary (Bhatia, Nigam, Bohra, & Malik, 1991; Szatmari et al., 1989b; Tao, 1992). Such variation may reflect true differences in prevalence but is more often thought to arise from differences with respect to assessment procedures, classification systems, standards for demarcating normal from disordered behavior, and culturally biased perceptions of behaviors (American Psychiatric Association, 1994; Chandra, 1993; Reid, 1995; Taylor, 1989). Although some studies have suggested a lack of uniformity in the rates of ADHD-related behaviors across socioeconomic and ethnic lines (e.g. Goyette, et al., 1978; Stevens, 1981; Waechter, Anderson, Juarez, Langsdorf, & Madrigal, 1979), findings in this area have been mixed.

Cross-national studies have been too few and methodologically different to warrant firm findings, but some evidence suggests that both the rates of the disorder and its definition may vary as a function of child-rearing values and gender roles in different cultures. A rating scale study of 344 second through fourth graders in Italian schools showed a markedly higher rate of hyperactivity in Italian boys (20%) than comparable US norms. The rate for girls was only 3%. Although Italian children exhibited rates of hyperactive behaviors similar to those of children in New Zealand, Spain, and portions of the USA, factor structures of the ratings for boys and girls were different, suggesting the need for separate factor analyses for males and females in cross-national research. Hyperactivity and conduct problems, in fact, were separate factors for girls, whereas such behaviors were subsumed under a single factor for boys. There were also important similarities and differences with the factor structures for boys and girls in Italy and Spain. These differences were interpreted as reflecting differences in the cultural acceptability of certain behaviors in Italy and Spain (O'Leary, Vivian, & Nisi, 1985). Notable cultural and ethnic differences in prevalence have been reported for Mexican and African-American studies of hyperactivity and ADD (Juarez, Madrigal, & Anderson, 1981; Lansdorf, 1979; Solis & Solis, 1988; Waechter et al., 1979). A teacher rating scale study was carried out in 2770 Chinese children from elementary schools in urban, suburban, and mountain communities. Prevalence rates of hyperactivity varied from 3.1% in urban areas, to 7.8% in suburban, and 7% in mountain communities (Yu, Yu, & Xiao, 1985). The suburban rates are closely comparable to the rate of 8.76% found in comparably aged recent Chinese immigrants (Yao, Solanto, & Wender, 1988). The marked regional differences contrast with relatively minor regional effects in national surveys within the USA (Achenbach, Conners, Quay, Verhulst, & Howell, 1989; Achenbach, Howell, Quay, & Conners, 1991) perhaps reflecting a greater range of regional differences in economic and social circumstances in the Chinese sample.

5.19.4.3 Comorbidity

Community-based studies show that many of the socioeconomic, gender, and family dysfunction factors associated with ADHD disappear when influences of comorbidity are statistically controlled (Szatmari et al., 1989a). Children of parents with diagnoses of panic disorder, major depressive disorder, or no diagnosis show marked differences in the rates of diagnosed attention-deficit disorders. The comorbidity of ADD and anxiety and/or depressive disorders was examined in 163 7–17-year-old offspring of parents with panic, depression, or no diagnoses. Diagnoses of ADD by self-report, parent report, and best-estimate consensus were all higher in the offspring of affected parents. Much higher rates of ADHD were reported when anxiety and/or depression were present in the child as well (McClellan, Rubert, Reichler, & Sylvester, 1990).

5.19.4.4 Developmental Factors

A major problem with categorical diagnostic schemes such as *DSM* is that fixed numbers of symptoms are required, and the normative rate of symptoms may change with age. For this reason, authoritative sources recommend supplementing *DSM* categorical criteria with norm-based symptom criteria (Barkley, 1990). The problem of syndromal definition is further complicated by differences in age trends for hyperactive–impulsive symptoms and inattention symptoms. Biological parents of hyperactive–impulsive children, compared with adoptive parents, show clear evidence of inattention but no hyperactivity–impulsivity, suggesting that the familial or genetic trait of hyperactivity-impulsivity tends to disappear in adolescence or adulthood (Alberts, Firestone, & Goodman, 1986). This finding is consistent with long-term follow-up studies which also suggest age-related changes in symptomatology (Hechtman, 1989; Weiss & Hechtman, 1986).

Although there is little doubt regarding age-related changes in the level of symptomatology, a more important issue is whether the syndromal structure is similar across ages. If not, then one could reasonably argue that a different appellation, such as "residual state," might be needed instead of the same diagnostic label that is used in childhood. In a recent study of a large national sample, both parents and teachers rated the 18 *DSM-IV* symptoms on a four-point Likert scale (not at all, just a little, pretty much, very much). Three different models of the factor structure were tested: a single linear factor; a hyperactivity–impulsivity and inattention two-factor model; and a hyperactivity–impulsivity–inattention three-factor model. For both parents and teachers the three-factor model provided the best fit to the data across all age groups (3–17 years), using stringent goodness-of-fit criteria. However, for practical purposes the two-factor model is probably sufficient, given a high correlation between the hyperactivity and impulsivity item clusters (Conners et al., 1996). This study clearly showed strong age-related declines in hyperactivity–impulsivity, whereas inattention tended to remain constant across the age groups. This cross-sectional study replicates a similar finding from the study of 7–12-year-old males with ADHD diagnoses followed longitudinally over a four year period (Hart et al., 1995).

5.19.5 ETIOLOGY AND RISK FACTORS

Modern concepts of disease emphasize that diseases are best conceptualized as a product of accumulated risks. There are many pathogens that require certain factors in the host before the disease will manifest itself. There are many protective factors, both biological and social, that operate in the host to ward off disease. Various contributing factors, such as genetic influences, neonatal and perinatal insults to the brain, normal variability of temperament patterns, and environmental risks and protective factors, interact in complex ways to produce the final behavioral outcome in a child. Considerable research demonstrates that many psychological and psychosocial phenomena are the result of biological risks (Rutter & Casaer, 1991). This concept is important because it frames the nature of research questions—

instead of asking: What is the cause of ADHD? with its implicit assumption of a single etiological pathway, it directs researchers to ask: What are the various combinations of risks and protections that produce the syndrome of ADHD?

The concept of risk factors is important for prevention, assessment, and treatment. Some environmental risks can be eliminated altogether, such as eliminating air-borne lead or other pollutants, preventing maternal smoking or drinking during pregnancy, or providing adequate nutrition to the developing brain. An understanding of biological risks is also important in the assessment and treatment process because knowledge regarding biological sources of ADHD helps parents by ameliorating guilt, develops rapport during assessment, and promotes positive attitudes towards the child and the family by minimizing blame and scapegoating. The role of biological risks in producing the syndrome has been important in gaining acceptance for school-based interventions for ADHD as one of the legitimate handicapping conditions.

Protective factors can offset or ameliorate the impact of risks, even when those risks are at the severe end of the spectrum (Werner & Smith, 1967; Werner et al., 1968). Good parenting, achievement orientation and the value of effort, socioeconomic advantage, educational opportunity, good diets, antistress techniques, and positive lifestyles, can all minimize otherwise disastrous effects of biological and environmental risks. The most important protective factors are social, parental, and educational. These form the basis of therapeutic efforts with ADHD children.

Among the most important risk factors for ADHD are various comorbid conditions that may occur along with ADHD. These conditions—anxiety, aggression, oppositionality, depression—may occur as genetically linked risks, secondary consequences, or simply as independently occurring processes. Some conditions, such as low self-esteem and demoralization, are almost inevitable secondary consequences of ADHD itself. Demoralization, depression, and anxiety frequently become part of the adolescent and adult picture of the disorder as the result of cumulative insults to self-esteem and failure in social and educational settings.

5.19.5.1 Genetic Risk Factors

Although no single marker for genetic transmission of ADHD has been found, comprehensive review of the neurobiological literature strongly suggests genetic and biological explanation for the syndrome (Zametkin, 1989). Overviews of the literature on genetic, biochemical, neurobehavioral, and neuroanatomical correlates of ADHD suggest that motor-regulatory systems involving subcortical and frontal systems are associated with ADHD. These studies also suggest a possible genetic basis because they implicate deficiencies in several neurotransmitters and because family studies show some concordance between affected parents and their children (Hynd, Hern, Voeller, & Marshall, 1991; McMahon, 1981).

Controlled case studies provide strong suggestions of genetic influences on hyperactivity and disruptive behavior (Heffron, Martin, & Welsh, 1984). Furthermore, more recent research applying powerful multiple regression techniques strongly suggests that ADHD is highly heritable (Gillis, Gilger, Pennington, & DeFries, 1992), with heritability estimates of 0.87–0.98. These estimates were similar to more recent data from hyperactive twins studied in London. Data from mixed-sex pairs did not support a two-threshold genetic explanation for the male excess of hyperactivity. The link between adverse family factors and hyperactivity was weak (Stevenson, 1992). Evidence suggests that only some forms of ADHD may be genetic, with the milder (situational) types showing less genetic influence and more association with antisocial behavior. These findings cast doubt on the validity of combining situational and pervasive hyperactivity into a single diagnostic category of ADHD, and also support a frequent finding that antisocial behaviour carries a different genetic pattern than ADHD (Goodman & Stevenson, 1989a, 1989b).

Family-genetic studies show that there are a number of associated risks shared with ADD, including conduct disorders, anxiety, depression, antisocial behavior, alcoholism, maternal personality disorders, and proneness to substance abuse in the first-degree relatives of ADHD (Cantwell, 1988). Relatives of ADD probands have a higher morbidity risk for ADD, antisocial disorders, and mood disorders than relatives of psychiatric and normal controls. The increased risk for ADD, however, cannot be accounted for by gender or generation of relative, the age of proband, social class, or the intactness of the family (Biederman, Faraone, Keenan, Knee, & Tsuang, 1990). Similar risks are found in ADHD girls as found in boys (Faraone, Biederman, Keenan, & Tsuang, 1991a). There are particularly high risks for offspring of parents with conduct, oppositional, or antisocial disorders (Faraone, Biederman, Keenan & Tsuang, 1991b). Further evidence of the genetic link to behavior problems comes from studies using parent ratings rather than diagnoses (O'Connor, Foch, Sherry, & Plomin, 1980). A classical twin analysis compared intraclass correlations for 54 pairs of identical twins and 38 pairs of same-sex fraternal twins, using a revised form of a parent symptom rating questionnaire (Conners, 1970). For seven of eight factor scales, correlations were significantly greater for the identical than for the fraternal twins. The identical twin correlations were similar to the test–retest reliabilities of the scales, suggesting that nearly all of the reliable variance for these behavioral problems was shared by identical twins.

There is a surprising link between familial ADHD and anxiety disorders (Biederman, Faraone, Keenan, Steingard, & Tsuang, 1991). Risk of anxiety disorders was twice as high in relatives of ADD when accompanied by an anxiety disorder than in those of ADD without anxiety disorder; there was also a tendency for relatives who had ADD to have a greater risk for anxiety disorders than relatives without ADD. Similar findings hold for affective disorders (Biederman, Newcorn, & Sprich, 1991). Some genetic risks may involve specific influences upon the early development of the fetus, as evidenced by the incidence of dysmorphology in the first-degree relatives of ADHD (Deutsch, Matthysse, Swanson, & Farkas, 1990). These studies suggest genetic heterogeneity for the disorder, and the possible value of dividing the disorder into more than one biological subtype.

Comorbidity of ADHD and learning disorders is high, with estimates ranging from 20% to 50%. It is not yet clear whether ADHD and reading disorders (RD) are genetically related or independent. Monozygotic and dizygotic twin pairs, in which at least one member of each pair was RD, were assessed for ADHD. Trends in the data and subtype analyses suggest that in some cases RD and ADHD may occur together because of a shared genetic etiology, and that a genetically mediated comorbid subtype may exist (Gilger, Pennington, & DeFries, 1992). Moreover, the specific type of learning disorder may be genetically determined, with phonological coding (i.e., sound-based reading) showing high heritability, while orthographic coding (i.e., visually based reading) shows no heritability. Phonological coding was substantially lower for most ADHD children with reading disabilities, indicating a developmental deficit in phonological coding rather than an equal developmental lag across all component reading skills (Olson, Rack, Conners, DeFries, & Fulker, 1991; Olson, Wise, Conners, & Rack, 1990; Olson, Wise, Conners, Rack, & Fulker, 1989).

5.19.5.2 Medical and Environmental Risk Factors

Medical factors are sometimes important because of their intertwined relationship to parenting variables and other aspects of social development. For example, low birthweight influences not only physical and cognitive competencies, but the behavior of mothers towards the child (Landry, Chapieski, Richardson, Palmer, & Hall, 1990). In a similar study (Lewis & Bendersky, 1989), independent impacts of severe intraventricular hemorrhage, other common medical complications of prematurity, and socioeconomic status, on the development in the second year of life were moderated by both the socioeconomic circumstances and the degree of medical complications.

Medical services are highly overused by ADHD children and families, even though mental health services are underused by ADHD children (Offord et al., 1987; Szatmari et al., 1989a). One reason may be that ADHD children have more actual psychosocial events leading to medical care than normal children. In one study they had more than twice as many actual medical and psychosocial events involving significant threat to the child. The causal direction of some of these risks is uncertain since many of the events may reflect the impulsivity and risk-taking behaviors of the children, and adverse environmental variables may be correlated through their relationship with comorbid conditions (Jensen, Shervette, Xenakis, & Bain, 1988).

5.19.5.3 Metabolic and Nutritional Factors

Metabolic and nutritional explanations of hyperkinesis have been around at least since 1929 when a report described a 12-year-old boy who,

> had been termed by psychiatrists and psychologists a "nervous hyperkinetic child." To use his own words, "I have to keep on going and be doing something ... " His diet was meager in meats and vegetables and rich in candy and cookies. This inadequacy of diet allied with hyperkinesis suggested the treatment. (Seham & Seham, 1929, p. 1)

Although comprehensive reviews of the role of nutrients, food additives, and sugar generally indicate a somewhat limited basis for inferring relationship to the etiology of ADHD (Milich, Wolraich, & Lindgren, 1986; Wolraich, Wilson, & White, 1995), current evidence suggests a complex intertwining of nutritional variables, such as sugar intake, exposure to environmental toxins, and other risk factors. Consider, for example, the role of cadmium and zinc. Cadmium is frequently inhaled from sidestream smoke by children (i.e., secondary smoke from smoking adults in the near environment). A large study of hair cadmium on the eastern shore of Maryland (Thatcher, McAlaster, Lester, & Cantor, 1984) found that children with high cadmium levels had lower IQ and poorer reading ability than those with low cadmium levels. However, this effect did not hold for children who regularly ate whole-wheat bread. Statistical controls ruled out demographic variables as causes. This unlikely phenomenon was found to depend upon the intake of zinc in the wheat kernel. The cadmium effect was inversely related to the levels of zinc measured in the children. The authors concluded that dietary zinc protects against the toxic effects of cadmium. Dietary intake of carbohydrate was also inversely related to the levels of zinc, a replicated finding in several studies for both micronutrients and vitamins (see below for further discussion of dietary risk factors). Thus, excess dietary sugar was found to have an important negative effect via its impact upon intake of needed dietary zinc. Even with socioeconomic status (SES) and other background factors controlled statistically, a multiple regression indicated that 20% of variance in reading level was accounted for by the combination of cadmium and the dietary factors.

5.19.5.4 Lead

The Centers for Disease Control (CDC) have published a major revision of their 1985 statement on prevention of lead poisoning in children (CDC, 1991). New evidence supports DHHS Secretary Louis Sullivan's assertion that lead is the number one environmental health threat to American children [Letters to the Editor, 1992]. The evidence linking low levels of lead exposure (10 μg or more per deciliter of whole blood), and a constellation of neurotoxic and other adverse effects in young children, is compelling. One study found that each 10 μg dl^{-1} increase in lead lowered IQ by eight points. The importance of lead as a subtyping factor in hyperactive children has been somewhat controversial, but considerable evidence suggests a relationship (David, Hoffman, Sverd, & Clark, 1977). Lead becomes especially important as the range of sociodemographic factors is increased and the risks of exposure are greater. Living in a crowded, urban neighborhood with high lead levels in older houses close to the increased lead deposition from automobile fumes, in combination with lower levels of nutrients such as calcium and iron, combines multiple risks. Calcium and iron protect against lead assimilation into the brain and gut, but are more likely to be absent from the child's diet if mothers (especially single mothers) start them earlier on cow's milk in order to return to work. Since the iron in cow's milk is less assimilable than breast milk, socioeconomic and nutritional risks interact. This form of complex interaction among risk factors may be the rule rather than the exception, making specific etiological or causal factors in ADHD difficult to disentangle.

5.19.5.5 Vitamins and General Nutrition

Several studies suggest a complex path relating hyperactivity, inattention, and cognitive function to nutritional status. Benton and Roberts (1988) reported that taking a vitamin and mineral supplement over an eight month period increased the nonverbal intelligence of 12-year-old British schoolchildren. The study was a well-designed double-blind placebo-controlled trial. This trial attracted considerable attention, and several replication studies appeared. A large study involving 615 US schoolchildren was carried out over a 12 month period of supplementation. The tablets contained either placebo or vitamins and minerals at 50%, 100%, and 200% of the US recommended daily allowance. Significant improvement in nonverbal intelligence was found for the 100% supplementation group compared with placebo. Equally important is the replicated finding of decline in performance IQ in the placebo-treated group (Benton & Buts, 1990). The cause of the apparent increase in nonverbal IQ with supplementation, and decline with the passage of time, is unclear.

Benton and Cook (1991) reported a study of 47 six-year-old children with a randomized double-blind procedure aimed at finding the nutritional and behavioral factors responsible. They found a 7.6 point IQ gain in the supplement group compared with a decline of 1.7 points in the placebo controls. Nutritional analyses revealed a strong positive relationship ($r = 0.55$, $P < 0.004$) between the amount of sugar in the diet and the change in IQ scores for three different IQ tests. The authors interpreted the findings to mean that high sugar intake is associated with vitamin deficiencies, which in turn result in lower IQ test results, mediated by effects upon attention and distractibility during testing. Supplementation is therefore more effective in children with the worst diets, that is, those who ingest excessive levels of carbohydrates and sugar. The argument was supported by direct observation by trained observers blind to the experimental conditions, showing that fidgeting and frustratibility during IQ testing showed a significant improvement in the supplemented group but not the placebo group.

The fact of excess sugar intake among children presenting for clinical services is indisputable. Its interpretation, however, is problematical. Dietary factors (e.g., high carbohydrate intake) may account for poor nutrition, but might also represent some correlated effect from social class or family characteristics. For example, the fact that children in the lowest quartile of attention are in the highest quartile of refined sugar intake was found to be related to parental license in giving access to the refrigerator (Prinz & Riddle, 1986). Available evidence of this type does not make it possible to determine (i) whether parents who are poor limit-setters produce uncontrolled children whose diets simply reflect another area in which the children lack self-control, or (ii) whether lack of dietary control leads to poor nutrition and thence poor cognitive and behavioral control.

These issues assume particular importance in patients from lower income groups since it is well known that poorer education and lower income are associated with poorer dietary status. We believe that there is a subgroup of ADHD children who are defined by the facts that they come from the lower part of the SES distribution. They routinely have poor dietary intake of vitamins and micronutrients; have relatively high carbohydrate to protein intake, and are lower in performance IQ than equivalent SES patients with good nutritional status. Nutritionally defined subgroups within the lower SES category may be an important predictor of developmental course and stimulant treatment response.

5.19.5.6 Temperament as a Risk Factor for ADHD

It has long been suspected that normal variations in temperament can dispose to later problems of ADHD. Certain extremes of normal temperament might become disorders when they conflict with parental styles or environmental requirements, despite being normal biological variations. There is little doubt that activity level is highly heritable and is normally distributed in the population (Conners & Kronsberg, 1985). In one study, Boudreault and Thivierge (1986) examined the relationship between temperament and externalizing- or internalizing-type behavior problems in school in 295 male and 301 female seven-year-olds. A temperament questionnaire was filled out by parents and the Conners Teacher Questionnaire was completed by teachers twice over a four week interval. The results indicated that a temperamental pattern of high activity and high approach with new stimuli predisposed boys to present externalizing behavior problems in school, whereas the temperamental traits of low adaptability or withdrawal with new stimuli predisposed girls to internalizing behavior problems in school. Others report relationships between parent ratings of adjustment problems and early temperament (Brody, Stoneman, & Burke, 1988). Long-term follow-up studies suggest that the adult outcome of ADHD may be related to early temperament styles (Hechtman, 1991). Predictions of long-term outcome based upon early temperament holds up in follow-up studies of epidemiological samples (Lambert, 1988).

One novel hypothesis considers vigilant attention as a temperamental trait. Weinberg and Brumback. (1990) suggest that the trait of vigilance has behaviors which overlap those of attention deficit–hyperactivity disorder. Vigilance is the state of being watchful, awake, and alert. Motor restlessness (fidgeting and moving about, yawning and stretching, talkativeness, or a combination of these) may be a method to improve alertness when sitting or standing still or when involved in tasks requiring continuous mental performance. In order to stay awake when prevented from being active, persons with lowered vigilance will stare off, daydream, show minor hyperactivity, and finally may fall asleep. They will also complain of boredom and monotony and usually avoid or lose interest in structured or repetitive activities. This trait is viewed as a dominantly inherited condition with onset in early childhood and worsening with age. Persons with this "primary disorder of vigilance" are described as having a remarkably kind and caring temperament. This description could be seen as simply another way of viewing ADHD; however, casting it as an inherited temperament trait has heuristic value since it shifts the search for etiology to extremes of normal temperament variation, rather than to a pathological process.

Short sleep durations and high ADHD symptom ratings appear to be features of children with a difficult temperament or high motor activity when awake and asleep. Thus, some children with colic (which is a common finding in the early history of ADHD children), may represent an extreme of a normal temperament trait (Weissbluth,1983, 1984).

5.19.5.7 Overview of Etiology and Risk Factors

It seems obvious that many different genetic, medical, temperamental and environmental risks can produce symptoms indistinguishable from ADHD. If extreme enough, virtually any single factor can, by itself, lead to the syndrome. However, it is seldom the case that single risk factors occur; rather, it is not uncommon to see family-genetic, medical, and other risks occur in combination. Development is transactional, so that risk factors create effects which then become a part of the ADHD picture; this new picture then leads to further complications, and so on. The high risks associated with maternal smoking or alcohol use (Nichols & Chen, 1981) are themselves linked to certain family psychiatric disorders as well as to the family environment of the mother and the toxic smoking environment of the child. In our view, then, the task of assessment in ADHD must focus on the understanding of the past and present risks, protective factors, and their interaction. The task of treatment is to maximize the protective factors while applying available remedies aimed at the biological substrata of behavior.

5.19.6 DEVELOPMENTAL COURSE AND OUTCOME

Results of longitudinal studies reported in the 1980s and early 1990s dramatically altered the prevailing view of ADHD as a disorder with symptoms that remit following puberty. In contrast to this putative benign course, these prospective investigations have revealed ADHD to be a typically chronic condition, marked by the persistence of symptoms into adolescence and often into adult life for the majority of children diagnosed with the disorder (Klein & Mannuzza, 1991; Weiss & Hecthman, 1993).

More than two-thirds of adolescents who were diagnosed with ADHD (by whatever label) in childhood continue to meet diagnostic criteria for the disorder, although the manifestations of the syndrome are likely to change over time, as discussed above (Barkley et al., 1990; Gittelman et al., 1985; Hart et al., 1995). Beyond the continuity of ADHD features, this group is characterized by rates of academic underachievement, school failure, low self-esteem, peer rejection, substance abuse, delinquency, and family disharmony that exceed those found among control subjects (Barkley et al., 1990; Faigel, Sznajderman, Tishby, Turel & Pinus, 1995; Fischer, Barkley, Edelbrock, & Smallish, 1990; Gittelman et al., 1985).

This pattern of persistent symptoms and heightened risk for negative outcomes across a broad spectrum of functional domains also appears to apply to at least half of the adults who received ADHD diagnoses as children. Investigations of this population are fewer and results more variable than for adolescents. Nevertheless, the emerging literature indicates the persistence of impairing ADHD symptomatology in a majority of cases along with generally lower levels of educational and occupational attainment and higher levels of job instability, substance abuse, antisocial behavior, and psychological distress than found in matched control groups (Barkley, Murphy, & Kwasnik, 1996; Biederman et al., 1995; Mannuzza, Gittelman-Klein, Bessler, Malloy, & LaPadula, 1993; Weiss & Hecthman, 1993). However, a number of carefully conducted studies have not found elevated rates of mood or anxiety disorders in adults with histories of ADHD (Gittelman et al., 1985; Mannuzza et al., 1993).

Despite this sobering outcome for many children with ADHD, it is important to note that a substantial proportion do indeed experience symptom remission and develop into well-adjusted, productive adults. Weiss and Hechtman (1993) estimate that up to one-third or more of children with ADHD may become indistinguishable from normal controls during adulthood. Thus, the heterogeneity that characterizes so many aspects of ADHD also applies to its course and outcome. Predictors of outcome, however, defy easy identification and are likely to involve complex interactions between a host of child, family, and ecological variables. The confounding of various predictors in many ADHD children can lead to misleading conclusions. For example, evidence suggests that the aforementioned link between childhood ADHD and later substance abuse is indirect; ADHD behaviors only increase the risk for substance abuse when they are accompanied by antisocial behavior patterns in childhood and it is the antisocial behavior rather than the early ADHD that predicts substance abuse (Lynskey & Fergusson, 1995). Similarly, aggression or other signs of conduct disorder may mediate the association between ADHD and later criminality and antisocial spectrum disorders (Hinshaw, 1994; Klein & Mannuzza, 1991). Clearly, the links between childhood externalizing symptoms and a variety of outcomes may be highly specific yet difficult to elucidate in the context of complex, multivariate causal chains.

5.19.7 CONCEPTUALIZATION AND CLINICAL FORMULATION

5.19.7.1 Multimodal Assessment

There has been no dearth of assessment research in ADHD. A recent synthesis of this literature commissioned by the Office of Special Education evaluated over 1300 references

(McKinney, Montague, & Hocutt; 1993). Along with many others (Angold, 1989; Barkley, Fischer, Newby, & Breen, 1988; Luiselli, 1991; McConaughy, 1993a; Morris & Collier, 1987; Ostrom & Jenson, 1988; Schaughency & Rothlind, 1991a), the authors of this synthesis assert that ADHD assessment should involve multiple informants, rely upon multiple technologies (ratings, interviews, direct observations, laboratory measures, and self-reports), cover multiple domains (home, school, peers, intra- and interpersonal functioning), and allow for a functional analysis that specifies treatment needs.

The major problem with these multilevel assessments is how to integrate information across informants and domains in such a way that the needs of both diagnosis and treatment formulation are served. Achenbach and colleagues made an attempt to formalize such a system using a multiaxial, cross-informant typology (Achenbach, 1992; McConaughy, 1993a). That approach has spawned vigorous debate (Macmann, Barnett, & Lopez, 1993; Martens, 1993; McConaughy, 1993b) and empirical validation has not yet occurred. In general, a best-estimate diagnosis is recommended by most authors, though rules for decision making and integration of information are usually left unspecified.

Experienced clinicians typically recommend a comprehensive evaluation that includes (i) a history of pregnancy, delivery, and developmental milestones from infancy; (ii) a family history of psychiatric disorders; (iii) assessment of specific symptoms, including their severity and frequency, situational specificity, and duration; (iv) an educational assessment which covers both academic functioning and classroom behavior; (v) intrapsychic processes, including self-image and sense of efficacy with family, peers, and school; (v) child and family interaction patterns and family structure; and (vii) neurological status when indicated by other evidence (Weiss & Hechtman, 1993). Although such an elaborate process provides a wealth of data, it does little to set boundaries around the disorder or to specify which treatments, in which combinations should be given; and it provides no clear operational methods for determining when treatment works.

Concerns about operational measures and lack of norms regarding attentional processes, and lack of consensual diagnostic criteria have prompted some to caution school psychologists against the diagnostic enterprise altogether (Ostrom & Jenson, 1988). They argue that there is a lack of a consensual definition of the disorder; that empirical research and theory have not isolated the particular attentional processes in question; and that there are no adequately normed measures of attentional processes alleged to cause the disorder. Instead, they recommend identification of the pattern of strengths and weaknesses, direct observations in the classroom with a normal control (response discrepancy), and a multigating approach (teacher identification, selection of the most severe cases, followed by school psychologist's evaluation of on-task behavior in the classroom and positive and negative social interactions at recess). This represents a more practical approach within schools and is responsive to treatment needs. However, from a broader perspective, this approach ignores the chronic long-term nature of ADHD, the role of medical treatment needs, and the treatments relating to home environment and social processes outside the school. It makes the assumption that all that is going on with these children is available to the naked eye, and that neurocognitive processes can be readily managed by strictly behavioral means. Throwing away everything we have learned about the biosocial nature of this disorder seems a heavy price to pay for the clarity of a strictly behavioral approach.

McKinney et al. (1993) were also disappointed at the paucity of studies assessing educationally relevant variables that specify how inattention, impulsivity, and overactivity impair learning on specific instructional tasks and in different educational settings. In response to this challenge, DuPaul and Stoner (1994) recommend a five-stage process of school-based assessment which starts with a teacher complaint involving one or more of the three main symptom categories (inattention, impulsivity, or overactivity): (i) use of normed teacher ratings of ADHD symptoms, followed by a multimethod assessment involving parent and teacher interviews; (ii) review of school records; (iii) behavior rating scales; (iv) observations of inclass behavior; and (v) academic performance data. A diagnostic formulation is made based on the number of ADHD symptoms, their deviance from age and gender norms, age of onset and chronicity, pervasiveness across situations, degree of functional impairment, and the presence of other disorders. A treatment plan is then developed which takes into account the severity of the symptoms, a functional analysis of behavior, the presence of associated disorders, response to prior treatment, and community-based resources. This is then followed by periodic collection of assessment data and a revision of the plan as necessary.

This approach is comprehensive, incorporates most current knowledge regarding ADHD, and reflects state-of-the-art clinical practice. However, it is both costly and potentially burdensome for the school system to undertake and inevitably extend services into the broader mental health system. An unanswered question is whether a straightforward approach which starts with the teacher's complaint, observes the behavior in the classroom, and immediately applies behavioral interventions without a broader diagnostic process involving labeling works as well as the more comprehensive five-stage process outlined by DuPaul and Stoner. Here, the assessment would be limited strictly to procedures which impact upon intervention, such as rates of deviant behaviors or academic functioning using curriculum-based measurement. An example is an eight-year-old boy with ADHD who attended regular third grade classes at his local elementary school. During academic instruction, he frequently displayed disruptive behaviors that rarely occurred during the rest of the school day. A brief functional analysis showed that disruptive behaviors were maintained by escape from task demands. Curriculum-based assessment revealed that disruptive behavior occurred most frequently during specific seating and grouping arrangements. Finally the effectiveness of an intervention derived from the assessments showed an immediate reduction in disruptive behavior and an increase in appropriate behavior that lasted throughout the data collection period (Umbreit, 1995).

Schaughency and Rothlind (1991b) also recommend a multimethod approach to assessment directed at answering four questions: Does the child meet *DSM* diagnostic criteria? Does an alternative diagnosis or conceptualization account for his or her difficulties (differential diagnosis)? Does the child display the behaviors to a developmentally inappropriate extent? Do these behaviors impair the child's functioning in school, social relationships, and/or in the home? They suggest a structured diagnostic interview with multiple informants to answer the first and second questions (along with IQ and achievement data, if needed), and information on developmental course and onset; behavior rating scales with multiple informants to answer the third question; and sociometrics and archival data (referrals, grades, classroom performance, etc.) to answer the final question. They recommend a best-estimate diagnostic approach, and also agree that we do not yet know what aspects of attention are disordered or how to measure them. They argue that the better performance of ADHD children in structured situations limits the utility of structured tasks for assessment. Their recommendations seem appropriate for younger children, but omits self-report information which is necessary in older children and adolescents (Conners & Wells, 1985). Self-report becomes increasingly important as children get older and develop more comorbid internalizing symptomatology. Their suggestion of using a lay interviewer instrument such as the Diagnostic Interview for Children and Adolescents or Diagnostic Interview Schedule for Children has the major disadvantage that these instruments significantly overdiagnose psychiatric disorders. This would be likely to significantly overburden the already-strained resources of the schools. The use of sociometrics (Hops & Lewin, 1984), although ecologically valid, has enormous practical problems, not the least of which is the necessity of getting informed consent from parents of both the peers and the target child.

Although multimethod/multisource information could theoretically prevent some of the excesses of diagnosis which occur with single-instrument methods, the question of whether the limited incremental validity and costs of these approaches (Homatidis & Konstantareas, 1981) can be justified in school settings and managed-care environments remains to be seen. In any case, most would agree that assessment for diagnosis, and assessment for treatment, although overlapping, are not the same thing and therefore require complementary methods. Structured interviews provide information needed to determine the diagnosis, but provide little guidance regarding target behaviors or modes of intervention. To address the latter, specific classroom behavior and academic problems must be identified, along with the nature of the home environment, particularly with regard to parenting practices and skills. If more extended contact is impossible, as often happens for either economic or geographic reasons, one provides parents with a list of resources which includes information regarding token management systems, self-monitoring skills, behavior contracting, schools and the law, books, legal resources, classroom modifications which work with most ADHD children, resources for parenting skills training, and parent support groups.

Our own clinical practice in a university medical school setting typically proceeds by collecting as much "free" information ahead of time for which the client is not billed, including a biographical history filled out by parents, parent and teacher rating scales which are computer-scored and analyzed (Conners, 1989); a developmental history and temperament scale (Conners & March, 1993); a multidimensional anxiety scale (March, Sullivan, & Conners, 1996); and a child depression scale (Kovacs' Child Depression Inventory, 1993). Office interviews are then conducted with the parents using a semistructured *DSM-IV* interview for ADHD, ODD, and CD if screening questions indicate that the latter is relevant (Conners, Erhardt, & Sparrow, in press); and an interview regarding family-genetic, medical, temperamental, and environmental risk factors (Conners, in press). While this interview is being carried out, computerized testing is usually conducted, including a continuous performance test (Conners, 1994a, 1994b; Conners, March, Fiore, & Butcher, 1994). This process takes 1–2 hours of clinical time. A separate session is usually held to provide feedback and initiate treatment plans. Whether or not the child meets any criteria for a *DSM* disorder, specific behaviors or academic problems which triggered the referral must be assessed and treated. Sometimes this amounts to simple reassurance in overanxious parents; but often the nonpharmacologic interventions will be the same in these very mild cases as that for someone meeting full diagnostic criteria. Some authors argue that diagnosis is therefore a waste of time (Ostrom & Jenson, 1988).

5.19.7.2 Treatment Formulation

The heterogeneity of the ADHD population with respect to presenting symptoms and comorbid conditions dictates that intervention strategies be individually tailored and based on results of a comprehensive clinical assessment. Indeed, despite its methodological shortcomings, the multimodal treatment study conducted by Satterfield and colleagues suggests that long-term, highly individualized treatment plans devised on the basis of detailed assessments may improve long-term outcome for ADHD youngsters (Satterfield, Satterfield, & Schell, 1987). As emphasized by Mash and Terdel (1988), assessment and treatment should be highly integrated and mutually informing clinical activities. Formulations regarding the contexts within which interventions need to occur (e.g., home, school, or peer group) and the nature of those interventions (e.g., pharmacologic, behavioral, or pedagogic) should develop during the course of the evaluation. After intervention has begun, formal periodic assessments should take place as a means of monitoring the child's status relative to the baseline evaluation in order to inform decisions about the need to modify, add, or terminate treatments. For example, an intensification of school-based behavioral programs may be indicated on the basis of an assessment documenting an increase in teacher-reported classroom misbehavior.

The selections of specific treatments for ADHD children cannot at present be informed by any known cure, certain or simple etiology, or any consensus regarding the underlying nature of the disorder. Thus, clinicians must rely whenever possible on interventions with empirically validated efficacy for the primary treatment targets identified through the comprehensive assessment. Hence psychostimulant medications and behavior therapy delivered through parents, teachers, or direct contingency management approaches are the likely cornerstones of treatment programs for ADHD. The need for adjunctive interventions to complement these core treatment components should be anticipated for many children with ADHD. Moreover, clinicians should endeavor to clearly delineate the relevant targets for each treatment. For example, improved attention to tasks may be identified as a target of pharmacotherapy, whereas reduced oppositionality may represent a goal of parent training. The specific foci of treatment should reflect the chief presenting concerns of the parents and/or child and the deficits or problem areas uncovered by the assessment, with particular emphasis on those features that are most impairing to current functioning and most highly associated with poor prognosis. Thus, reducing aggressive behavior or redressing academic deficits may be prioritized as treatment goals despite such problems representing associated rather than primary features of ADHD.

Common to each planned treatment component should be programmatic efforts to promote generalization of gains across behaviors, settings, and time (Conners et al., 1994). Extending the duration of treatments (e.g., years versus months), which is consistent with the chronic nature of ADHD, may contribute to temporal generalization. Improved generalization may also result from incorporating significant others into treatment (e.g., parents, teachers, or peers), using diverse training experiences, and providing booster sessions.

Decisions related to the sequencing and cessation of various pharmacologic and psychosocial treatment components are complex and cannot as of yet be informed by a body of evidence from controlled studies. Ultimately, such decisions must be made on the basis of clinical judgment, following consideration of relevant factors such as symptom severity, age and developmental level of the child, comorbid symptoms or conditions, the palatability of various treatments to the child and family, and the extent of available resources, both within the family and the community. Some argue that behavioral interventions should always be initiated prior to medications (Hoza, Vallano,

& Pelham, 1995) but the demonstrated short-term efficacy of stimulant treatment in conjunction with its low cost and ease of administration relative to psychosocial interventions may provide some justification for introducing pharmacotherapy as the initial treatment component. Moreover, a favorable stimulant response may enhance the efficacy of subsequent interventions, although this has yet to be demonstrated empirically.

A final point related to treatment planning involves the coordination of clinical services. The adequate treatment of children with ADHD is typically a complex and lengthy process, the many facets of which are unlikely to be within any given practitioner's scope of competence. It is thus necessary for the individual clinician to be familiar with community resources that may be of benefit to ADHD children and their families and to establish the relationships with professionals from other disciplines that are necessary to develop coordinated, multimodal treatment plans.

5.19.8 TREATMENT

Two primary goals should guide the selection and implementation of interventions for children with ADHD: (i) optimizing current functioning across behavioral, academic, family, and social domains by reducing the severity and impact of core and associated symptoms; and (ii) prevention of the adverse outcomes known to result for many of these youngsters by intensively targeting those problem areas (such as aggression and other antisocial behaviors, academic underachievement or failure, family dysfunction, or peer rejection) most strongly associated with poor prognosis. In the light of these overarching goals and the multifaceted problems experienced by most children with ADHD, consensus has emerged that no single treatment is likely to be sufficient for addressing the acute and chronic clinical needs of this population. Clinical and research efforts have moved towards the identification of multimodal treatment packages with the hope that active components will interact in a complementary or synergistic fashion to maximize therapeutic effects (Abikoff & Hechtman, 1996; March, Wells, & Conners, 1995b; Pelham & Murphy, 1986; Richters et al., 1995).

5.19.8.1 Psychosocial Interventions

Despite the well-established short-term clinical efficacy of psychostimulant medications (March, Erhardt, Johnston, & Conners, 1995; Swanson et al., 1993), alternative or adjunctive psychosocial interventions are invariably required for one or more of the following reasons: (i) medications are not an option for a minority of children with ADHD due to nonresponse, intolerable side effects, or parent refusal; (ii) gains achieved by medication often fail to normalize functioning in the short term and have yet to be associated with long-term benefits; (iii) many associated symptoms of ADHD (e.g., academic skill deficits or family disharmony) are not appropriate targets for pharmacotherapy (as reflected in the adage "pills don't teach skills"); (iv) the restriction of stimulant-related benefits to times when the child is actively medicated often results in a need for other interventions to be in place during evenings, weekends, and vacations; and (v) the use of combination treatments may permit lower intensities or dosages of each component (e.g., lower medication dosages resulting from the presence of concurrent contingency management programs).

Prior to discussing a selection of the wide range of psychosocial treatments which have been applied to children with ADHD, we wish to highlight that behaviorally oriented interventions enacted through parents, teachers, or direct contingency management programs in the classroom represent the most widely applied and empirically supported psychosocial interventions for ADHD (Hinshaw & Erhardt, 1993; Pelham & Hinshaw, 1992). Although less common and less efficacious with ADHD populations, cognitive-behavioral interventions, social skill training programs, and individual child treatment also warrant comment due to their potential utility as adjunctive components in multimodal treatment packages. There are a number of additional interventions with limited or no established efficacy for ADHD populations, including dietary management, electroencephalographic biofeedback, relaxation training, ocular exercises, chiropractic methods, megavitamins, and sensory integration training.

5.19.8.1.1 Parent-based interventions

Following their successful application to children with oppositionality, aggression, and other conduct problems (Wells, 1995), parent training (PT) approaches were extended to ADHD populations in the early 1980s and have emerged as the most prevalent psychosocial treatment for the disorder. Two objectives which characterize PT programs for ADHD are educating parents about the disorder and teaching a comprehensive set of behavior management skills so that parents may act as change agents to reduce negative behavior and promote adaptive functioning in the natural environment. Efforts are also geared towards improving the general family emotional climate and altering coercive parent–child interactions which may contribute to the exacerbation of ADHD symptoms and oppositional behavior (Barkley, 1990; Campbell, 1990).

Detailed, session by session descriptions of PT programs are available (Anastopoulos & Barkley, 1990; Barkley, 1987; Hembree-Kigin & McNeil, 1995; McMahon & Forehand, in press; Newby, Fischer, & Roman, 1991). Despite some variation in format, duration, and content, PT programs for ADHD generally rely heavily on therapist modeling, behavior rehearsal (e.g., role playing), and homework and include the following components: (i) psychoeducation on ADHD; (ii) introduction to social learning theory and general behavior management principles; (iii) positive reinforcement skills (e.g., positive attending, "catch your child being good," promoting independent play, or effective ignoring); (iv) effective commands; (v) point or token economy systems; (vi) nonphysical punishment procedures (e.g., response cost or time out); and (vii) managing behavior outside of the home. (A valuable augmentation to the psychoeducational component of PT is parent involvement in an organization designed to support and provide information to families with children with ADHD and related disorders (e.g., Children and Adults with Attention Deficit Disorders).) Innovative additions to some recent PT programs have included stress and mood management for parents, interventions to enhance marital functioning, academic support skills for the home, inputs to improve peer functioning, and training parents to advocate effectively for their child at school (Wells, in press). Specialized interventions incorporating aspects of behavioral, cognitive, and family systems approaches have been developed for families with ADHD adolescents (Robin & Foster, 1989) and found to yield improvements to family functioning (Anastopoulos, Barkley, & Shelton, 1996).

Controlled studies of PT have found it to reduce primary and associated symptoms of ADHD and to have favorable effects on parenting stress and parenting self-esteem (Anastopoulos et al., 1996; Anastopoulos, Shelton, DuPaul, & Guevremont, 1993; Wells, in press). Despite their documented efficacy for ADHD, PT approaches do not appear to achieve the same magnitude of behavioral effects as pharmacotherapy, typically fail to normalize functioning, and place high demands on parents that can reduce compliance and maintenance of treatment effects (Hinshaw, 1994; Pelham & Hinshaw, 1992).

5.19.8.1.2 School-based interventions

Some form of classroom intervention is almost invariably indicated for children with ADHD due to the adverse impact of inattentive, overactive, impulsive, and associated symptoms on learning, performance of acquired skills, and adherence to class rules and routines. School-based treatment for ADHD children may comprise both academic (e.g., tutors or special education services) and behavioral interventions. The former (DuPaul & Stoner, 1994) are not reviewed here but are often indicated due to scholastic skill deficits and possible comorbid learning disorders. Rather, we focus on behavioral interventions designed to improve the child's ability to meet both comportment and academic demands at school.

A host of classroom interventions for ADHD address antecedents of behavior by making modifications to the classroom environment, materials, and instructional techniques in an effort to create a "prosthetic" environment that helps to minimize the impact of ADHD symptoms (Abramowitz, 1994; Pfiffner & O'Leary, 1993). Beneficial changes to classroom structure may involve establishing clear and salient class rules, arranging seating so that the child is distanced from likely distracters and surrounded by well-behaved peers, instituting highly consistent routines (e.g., for turning in completed homework), and insisting that students use a daily assignment book. Students with ADHD often show higher rates of on-task behavior and task completion through the use of timers, assignments that are shortened or divided into smaller parts, checklists outlining the steps involved in a task, and alternative response methods (e.g., oral reports and videotapes). Moreover, the effectiveness of instructional methods is likely to be enhanced when they incorporate higher levels of activity, stimulation, and novelty than is typical for most classrooms.

Another group of school-based treatments for ADHD focuses on manipulating the consequences of behavior. In direct contingency management approaches, a behavior therapist establishes formal reinforcement systems with clear guidelines for behaviors that both earn and lose tokens, which may subsequently be exchanged for tangible reinforcers (e.g., access to a rewarding classroom computer). Numerous studies have documented the effectiveness of such methods for improving both academic productivity and classroom behavior (Ayllon & Rosenbaum, 1977; Hinshaw & Erhardt, 1993; Pelham & Hinshaw, 1992).

More common, however, are models in which therapists consult with teachers in order to educate them about ADHD and teach effective instructional and behavior management strategies. Much of the content in such interventions parallels that found in PT, albeit with adaptations to ensure applicability to the school environment. Thus, teachers learn to make positive attention contingent upon desirable behavior, issue effective commands and reprimands, provide high rates of prompts and feedback, establish token economies specifying individual or group-based contingencies, use response cost and time out as punishments, and enact many of the antecedent modifications discussed above. Teachers, like parents, are encouraged to provide a high ratio of positive to negative consequences but also cautioned that prudent negative consequences, such as response cost and time out, are often essential components of behavioral programs for youngsters with ADHD (Abramowitz, 1994). Detailed discussions of these and additional school-based interventions for students with ADHD, including daily report cards (DRC), behavior contracts, self-monitoring and self-reinforcement, study and organizational skill training, and group-based contingencies can be found in DuPaul and Stoner (1994), Parker (1992), and Pfiffner and O'Leary (1993). Additionally, Burcham, Carlson, and Milich (1993) review key features of educational practices for ADHD judged to be most promising in a project of the US Department of Education.

DRC systems merit comment because they represent a widely used and highly effective intervention wherein daily rewards are issued or withheld by parents at home contingent upon the child's behavior at school. DRC systems begin with teachers and parents collaboratively identifying behavioral and academic goals which are tailored to the unique needs of the child (e.g., "follows teacher instructions promptly," "completes and turns in homework," and "remains seated when required"). Next teachers complete a brief checklist (or DRC) at predetermined times throughout the school day that indicates whether the child met his/her goals. The DRC is sent home with the child daily and parents either provide or withhold rewards depending on the child's performance. When used alone or in combination with classroom reinforcement programs, the home–school contingencies enacted through a DRC represent a powerful means of improving both academic performance and classroom behavior (Abramowitz, 1994). Additional advantages include their low cost, ease and brevity of use, incorporation of more potent reinforcers than may be available at school, and provision of regular communication between teachers and parents.

Despite the significant benefits associated with the implementation of these behavioral school interventions in research protocols (Abikoff & Gittelman, 1984; Abramowitz, 1994), they continue to be underutilized in clinical practice. Obstacles to implementation include inadequately funded school systems, lack of training among both school and mental-health personnel to provide behavioral consultation to teachers, and demands on teachers' time which limits the practicality of some interventions (DuPaul & Stoner, 1994; Reid, Vasa, Maag, & Wright, 1994). Efforts to improve the ease of implementation and palatability for such interventions need to receive high priority in light of the typically unmet needs of students with ADHD and the legal rights of these children to adjunctive educational services (Davila, Williams, & MacDonald, 1991).

5.19.8.1.3 Child-based interventions

(i) Cognitive-behavioral methods

The prospect of addressing ADHD with cognitive-behavioral (CB) interventions initially inspired much enthusiasm due to the theoretical appeal of matching the disorder with a treatment approach designed to foster planful self-regulation. Investigations of many types of CB procedures, including verbal self-instructions, problem solving strategies, attribution retraining, self-evaluation, self-reinforcement, and anger control training, have emerged since the mid-1970s. As concluded in earlier reviews (Abikoff, 1991; Hinshaw & Erhardt, 1991), this line of research has generally failed to yield strong support for the application of CB methods to ADHD populations, particularly with respect to the much hoped for generalization of treatment gains across time and settings. Results for procedures based on self-instructional training methods have been particularly dismal.

Nonetheless, some positive outcomes have been found for anger management training and for procedures where the child is taught to monitor, evaluate, and reinforce themselves with respect to particular target behaviors (Hinshaw & Erhardt, 1991). Anger-coping programs, which are typically conducted in a group format, focus on teaching children to recognize their unique anger cues, to develop cognitive or behavioral plans for coping with anger adaptively, and to practice implementing those plans under realistic, provocative circumstances, such as being taunted by peers. However, at least two preconditions need to be met in order for these or any other cognitive intervention to yield clinically significant and generalized gains in ADHD youngsters: (i) key adults in the child's life (parents and teachers) must be taught to model, prompt, and reinforce targeted skills; and (ii) extrinsic reinforcement programs must be initiated to reward the child for the display of cognitive skills. Another rarely mentioned but useful application of a CB approach for this population involves employing cognitive restructuring methods to challenge and modify maladaptive beliefs about ADHD held by parents and teachers which may hinder their implementation of other treatments. Braswell and Bloomquist (1991) offer a detailed description of the clinical applications of CB procedures with ADHD children.

(ii) Social skill training

Despite the often glaring social failures of youngsters with ADHD, traditional social skill training programs, emphasizing the acquisition of prosocial behaviors, do not appear to be generally effective in improving the peer functioning of this population (DuPaul & Stoner, 1994; Whalen & Henker, 1992). This may well relate to the fact that youngsters with ADHD, as a group, do not appear to be deficient in the targeted social skills *per se*, but rather show problems in skill performance in natural social settings along with elevated rates of socially noxious behaviors.

Hinshaw (1992c) notes the broad array of potential foci for interventions designed to improve the social competence of children with ADHD, including decreasing negative behaviors known to be associated with poor peer status (e.g., aggression), teaching deficient social skills, enhancing self-monitoring of social behavior, altering social goals (e.g., emphasizing affiliation over dominance), teaching social problem-solving skills, promoting more accurate social information processing, and improving academic performance. He argues that meaningful and durable change in the social arena is only likely to result from multifaceted, individually tailored interventions that are delivered in naturalistic settings over long periods of time in combination with pharmacologic treatments and behavioral reinforcement programs.

Guevremont (1990) has developed a program for enhancing peer functioning that is more comprehensive than those typically employed. The approach combines social and CB skill training with programming to promote generalization and strategic peer involvement. Also promising are the multipush efforts to address peer problems contained in the intensive summer day camp treatment programs developed by Pelham (Pelham & Hoza, 1996). In addition to behavioral instruction of specific social skills (e.g., communication and conflict resolution), children are taught anger management strategies, trained in sports and game skills, and continuously reinforced for the display of appropriate social behavior in highly naturalistic classroom and playground settings. Moreover, a "buddy system" encourages the development of dyadic friendships, which may buffer some of the consequences of being unpopular in the larger peer group.

(iii) Psychotherapy

There is no compelling evidence to support the use of individual psychotherapy to address the core symptoms of ADHD (Hinshaw, 1994). Nevertheless, the experience of repeated failures across domains and frequent negative feedback from both adults and peers can lead to low self-esteem, demoralization, and negative self-image in many children with ADHD. Such problems do represent legitimate foci of expressive and CB psychotherapies which thus should be considered as adjunctive treatments for some youths with ADHD. Indeed, the multimodal treatment study conducted by Abikoff and Hecthman (1996) included a psychotherapy component for which a specific manual was developed. Greenfield, Gottlieb, and Weiss (1992) discuss some of the indications, challenges, and adaptations associated with conducting individual psychotherapy with children with ADHD.

5.19.8.2 Pharmacologic Interventions

Stimulant drugs such as Ritalin (methylphenidate) or dexedrine (dextroamphetamine) have been well-documented in their ability to bring about almost instantaneous behavioral changes in a wide array of symptomatic behaviors in ADHD. It is this remarkable alteration of behaviors, usually impervious to ordinary blandishments by parents and teachers, that helped make ADHD one of the most researched disorders in the behavioral sciences (as well as controversial in the public sphere). Contrary to popular belief, however, the pharmacologic treatment of ADHD is not a simple matter. It is true that a few drugs are highly efficacious against a wide array of symptoms, and have few side effects or adverse long-term consequences. But there are many variables that affect results in individual cases, and the deceptive ease of use of these medicines often leads to casual management without concern for the overall treatment needs of the child and family. Detailed examination of pharmacologic strategies with

ADHD shows that physicians must engage in a complex algorithm for deciding which drug to use, at what dose, and in what form (Greenhill et al., in press). Comprehensive reviews of efficacy and safety of stimulant drugs with ADHD are available (Swanson, McBurnett, Christian, & Wigal, 1995), and the interrelationship among genetics, neuroimaging and the neuropharmacology of ADHD have been well-described (Ernst & Zametkin, 1995). Here, we will focus on the essential clinical phenomena that need to be understood as part of a comprehensive treatment approach to ADHD. Important variables to consider are patient selection, choice of drugs, dose–response, time–action, side effects, and measurement issues.

5.19.8.2.1 Patient selection

Several meta-analyses of drug studies are in agreement in showing that stimulant drugs are most efficacious for symptoms of hyperactivity and other externalizing behavior problems, and somewhat less so for cognitive and achievement problems (Kavale, 1982; Ottenbacher & Cooper, 1983; Thurber & Walker, 1983). The effect sizes in those studies are very large—about one standard deviation for behavioral symptoms, and about half that for cognitive and academic problems. Although it is generally thought that the stimulants are specifically indicated only for hyperactivity, comprehensive reviews show that in addition to the primary symptoms of motor restlessness, concentration, effortful attention to tasks, and self-regulation; stimulants also improve general deportment and compliance, reduce verbal and physical aggression, decrease negative social behaviors, and improve academic productivity and accuracy (Swanson, et al. 1995). Comorbid anxiety may reduce the level of effect from stimulants (Pliszka, 1989) and be better treated with antidepressants such as imipramine (Pliszka, 1987). The fact that normal children also show improved function with stimulants warns against the misconception that the response to stimulants is diagnostic (Rapoport et al., 1980).

5.19.8.2.2 Choice of drugs

There are three stimulants approved by the Food and Drug Administration to treat ADHD patients of all ages: dextroamphetamine (Dexedrine, manufactured by SmithKline-Beachem), methylphenidate (Ritalin, manufactured by CIBA-Geigy), and magnesium pemoline (Cylert, manufactured by Abbot Laboratories). Dextroamphetamine and methylphenidate are structurally related to the catecholamines, dopamine and norepinephrine, whereas pemoline exerts its action primarily through dopaminergic mechanisms (Greenhill, 1992). As noted in recent reviews (March, Erhardt, et al., 1995, March, Wells, & Conners, 1995b), these compounds tend to increase central nervous system (CNS) activity in some but not all brain regions. They increase the activity of striatum and connections between orbitofrontal and limbic regions, while having an inhibitory effect on the neocortex. Stimulants act by enhancing the release of catecholamines into the synaptic cleft, decreasing their reuptake and slowing down their degradation by inhibiting monoamine oxidase. Direct postsynaptic agonist activity is also postulated for dextroamphetamine and methylphenidate. Although catacholaminergic mechanisms are undoubtedly involved in the mechanism of action in ADHD—perhaps by favorably altering the processes by which the CNS allocates attentional resources and/or decides stimulus salience—the exact processes by which these compounds work remain uncertain (Zametkin & Rapoport, 1987).

5.19.8.2.3 Dose–response and time–action

Two essential aspects of stimulant treatment are constructing a dose–response curve and analyzing time–action effects. The former refers to the relationship between dose of drug and the presence of benefits and adverse effects. Establishing these relationships depends on understanding the relationship between the timing of administration, onset of response, point of maximum responsiveness, and loss or offset of drug effect. Empirical evidence suggests that dose and response are independent of body weight and that there is wide intersubject variability in response to the same dose (Rapport & Kelly, 1991). The time–action curve for attentional functioning is somewhat different from that of motor behavior (Solanto & Conners, 1982). Departures from a linear dose–response pattern are common, with some children showing a threshold effect (no response below a threshold level) and others a quadratic response (linear at lower doses and degradation at higher doses). Clinically then, each child requires an individually constructed dose–response curve, taking into consideration the time–action effects of the drug at each dose before making dosage adjustments (Erhardt & Conners, 1995). When titration is accomplished in the traditional open fashion, one starts with the lowest possible dose, working upward every 5–7 days until benefits are maximized or the patient shows prohibitive side effects.

Sprague and Sleator (1977) first suggested that the dose of methylphenidate required to achieve optimal effect for social behavior is higher than the dose required for cognitive function. They found that a high dose in a demanding memory task actually lowered performance below that of the placebo condition. Although there have been several failures to replicate findings of curvilinear dose–response effects with effortful cognitive tasks, some well-designed studies nevertheless continue to find that key attentional and academic measures show a quadratic relationship of dose and effect (Rapport, DuPaul, Stoner, & Jones, 1986). More recent reviews express concern regarding "cognitive toxicity" of high doses, particularly when the laboratory or academic task is difficult or complex (Aman & Rojahn, 1992; Swanson, Cantwell, Lerner, McBurnett, & Hanna, 1991). Interestingly, some studies (Rapport & Kelly, 1991) find that higher doses of stimulants are more effective as the task becomes more complex and demanding. Rapport and Kelly summarized a large number of cognitive tasks used in drug studies and reported that (i) in 100% of the studies the higher dose was better than the lower dose, and (ii) those judged more complex responded, in general, better to the higher dose (though individual group curves sometimes show curvilinear effects). In any case, the findings generally support the proposition that each child requires an individualized assessment in order to define the appropriate dose for the particular target behavior in question, whether behavioral or cognitive.

Dextroamphetamine is usually started at 2.5–5 mg a day and gradually increased in 2.5–5 mg increments; methylphenidate is usually started at 5 mg twice a day and then titrated in 5 mg per dose increments every 4–7 days. Peak behavioral effects are noted 1–3 hours after ingestion and dissipate in 3–6 hours for both methylphenidate and dextroamphetamine. Pemoline is usually started at 37.5 mg each morning and titrated in 18.75 mg increments to maximum clinical effectiveness. Most children respond at a total daily dose of 56.5–75 mg. Although stepped-dose open-label trials of stimulants are the rule in clinical practice, double-blind placebo-controlled titration trials, using parent and teacher ratings and objective measures of performance and academic productivity, can be very helpful in distinguishing a true drug effect from a placebo response and in establishing the best dose for an individual child.

Clinical experience suggests that sustained-release methylphenidate is variably absorbed and shows variable behavioral effects, whereas the dextroamphetamine spansule may show a more even pattern of bioavailability. However, since both tablet and sustained release stimulants are swiftly absorbed after oral administration, it is not surprising that controlled studies show no benefit for sustained release methylphenidate over the standard formulation (Pelham et al., 1987). The sustained release preparations are often helpful when the standard preparation dissipates too rapidly, or when there is stigma associated with going to the teacher or nurse for a midday dose.

5.19.8.2.4 Side effects

Frequent stimulant-related side effects and their management are summarized in Table 3. Since many side effects diminish after several weeks of treatment, patience during stepped-dose titration is important in handling mild to moderate side effects, such as mild anorexia or sleep disturbance. Sometimes gastrointestinal difficulties can be ameliorated by administration of stimulants before, during, or after meals, depending on the child. (In the child on pemoline, prominent gastrointestinal side effects, including but not limited to anorexia, should prompt consideration of pemoline-induced hepatitis since, though rare—less than 1%—it requires drug discontinuation.) Insomnia can sometimes be avoided by reducing the last dose or by earlier administration. Exacerbation of ADHD symptoms and/or irritable dysphoric mood during stimulant offset (stimulant rebound) is uncommon but can be disruptive, especially near the end of the day during homework periods. Rebound requires adjusting the dose or perhaps switching to a sustained release preparation or to a different stimulant.

Stimulants do not appear to adversely influence ultimate growth and height in most children, although a minority of children may be affected either because of calorie restriction or direct effects on growth hormone. Thus, routine drug holidays are not indicated; when necessary, periods off medication may bring about a rebound in growth rate. Caution is in order when using stimulants in children with a personal or family history of hallucinations or thought disorder, especially since attentional abnormalities are common in children at risk for schizophrenia. Close monitoring of blood pressure and pulse is not mandatory with stimulant treatment unless there is a pre-existing cardiovascular disorder, such as tachyarrythmias or hypertension. Because of the potential for transaminitis (an elevation of liver function enzymes), pemoline requires liver function test

Table 3 Side effects of stimulant drugs.

Side effect	*Possible management strategies*
For all side effects	Unless severe, allow 7–10 days for tolerance to develop. Evaluate dose–response relations Evaluate time–action effects and then adjust dosing intervals or switch to a sustained-release preparation Evaluate for concurrent conditions, including comorbidities and environmental stressors Consider switching stimulant drugs
Anorexia/dyspepsia	Administer before, during, or after meals If on pemoline, consider drug-induced hepatitis
Dysphoric mood/emotional construction	Reduce dose or switch to a long-acting preparation Consider comorbidity requiring alternative or adjunctive treatment Switch stimulants
Insomnia/nightmares	Omit or reduce last dose Administer medication earlier in the day If taking sustained-release preparation, switch to tablet drug Consider adding a sedating antihistamine or clonidine at bedtime only
Tics	Firmly establish correlation between tics and pharmacotherapy by examining dose–response relationships, including a no medication condition If tics are very mild or abate after 7–10 days on medication, reconsider risks and benefits of continued stimulant treatment and renew informed consent Switch stimulants Consider nonstimulant treatment, eg clonidine or a tricyclic antidepressant (TCA) If tic disorder and ADHD are severe, consider combining stimulant with a high-potency neuroleptic
Dizziness	Monitor blood pressure and pulse Encourage adequate hydration If associated only with peak effects, change to a sustained-release preparation Switch stimulants, especially to pemoline
Weight loss	Give drug after breakfast and after lunch Implement calorie enhancement strategies, especially a scheduled fourth meal before bedtime Brief drug holidays
Slowed growth	Apply weight loss remedies Weekend and vacation (longer) drug holidays Consider another stimulant or a nonstimulant drug
True rebound	Switch to sustained-release preparation or to pemoline Combine long- and short-acting preparations Consider combined psychostimulant (at a lower dose) with a TCA or switching to bupropion
Psychosis	Discontinue stimulant treatment Assess for comorbid thought disorder Consider alternative treatments

at baseline and every six months and should be discontinued if double-normal transaminases arise.

One of the major decisions in initiating drug therapy is which stimulant to prescribe in individual cases. In an early study, Millichap and Fowler (1967) randomly assigned 75 6–12-year-old children to dextroamphetamine, methylphenidate, or a placebo and found no differences between the two drugs on 11 behavioral laboratory measures or clinical rating measures. Although for every side effect examined dextroamphetamine had a higher frequency and severity, neither drug had a medically significant frequency of intolerable side effects requiring drug discontinuation. An early review of nine studies by Millichap and Fowler (1967) showed 84% efficacy for methylphenidate compared with 69% for dextroamphetamine, whereas Barkley's (1977) review of 14 methylphenidate and 15 dextroamphetamine studies found approximately equal efficacy with about 70% improvement rate for both stimulants (Arnold, Heustis, & Smeltzer, 1978). Although reasonably consistent, these results are all between-subject effects. Several studies which compare crossovers of the stimulants within subjects, show approximately equal efficacy overall, but not always for the same subjects (Pelham, et al., 1990; Winsberg, Press, Bialer, & Kupietz, 1974). Using a wide variety of social, academic, and behavioral measures, Pelham et al. (1990) also found that dextroamphetamine and methylphenidate were generally equivalent but that some subjects responded better to one drug than to the other. When dosages are raised to their maximum without side effects, the two stimulants are quite comparable in efficacy, but some children who respond to one do not respond to the other (Elia, Borcherding, Rapoport, & Keysor, 1991; Sallee, Stiller, & Perel, 1992). These studies imply that in clinical practice one should try alternative medications within the same class before going on to other classes of drugs. Pemoline shows comparable efficacy to the other stimulants but has had a perhaps unjustified reputation as being prone to produce toxic liver effects (Conners & Taylor, 1980; Conners, Taylor, Meo, Kurtz, & Fournier, 1972; Knights & Viets, 1975; Pelham et al., 1990), and should be considered along with other stimulants as a first-line drug for ADHD (March, Johnston, & Conners, 1996). Antidepressant drugs represent another class of drugs whose efficacy is satisfactory, but which carry higher risks for serious cardiovascular side effects (Gickling & Thompson, 1985; Ross, Poidevant, & Miner, 1995).

5.19.8.2.5 Measurement of drug treatment effects

Parent and teacher ratings have been the most widely used methods for assessing stimulant drug effects, and are considered an essential aspect of treatment monitoring. However, the considerations of dose and time–action effects described above suggests that multilevel assessment of drug effects is likely to be necessary in an optimal treatment regimen. Relying on behavioral ratings alone may jeopardize the cognitive function of the child if dosage is titrated upwards without regard to possible adverse effects on more subtle attentional and learning processes. Curriculum-based measurement uses the rate of learning in standard reading, spelling, or arithmetic tasks, using brief timed samples of performance. These methods have been successfully used in assessing and measuring treatment progress of ADHD children (Atkins & Pelham, 1991; Atkins, Pelham, & Licht, 1985). A number of classroom-based measures of academic productivity have been described which show good discriminative ability in differentiating ADHD children from controls. These methods appear to be sensitive to drug treatment and are certainly more ecologically valid than conventional standardized tests of academic function which tend to be insensitive to treatment (Balthazor, Wagner, & Pelham, 1991; Pelham, 1986; Pelham, Bender, Caddell, Booth, & Moorer, 1985; Pelham et al., 1987).

5.19.9 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

5.19.9.1 Future of Assessments of ADHD

Considerable advances have been made in our understanding of both the processes of attention and inhibition (Conners, March, Erhardt, Butcher, & Epstein, 1995). As yet, however, these newer approaches have not been accompanied by methods that are easily transported from the laboratory to the clinic. Nevertheless, computerized tests based upon neurocognitive models are likely to be available for use once adequate normative studies and validity studies are undertaken. These new approaches will be necessary to meet the justified criticisms of those who argue that the core features of ADHD have never been adequately operationalized. Equally important as assessments at the level of microprocesses of attention and inhibition, are larger family, social, and developmental issues, which at present are poorly assessed. Until assessments have an adequate treatment target, however, they had, perhaps, better be left alone.

5.19.9.2 System Issues in Treatment

One of the most common failings of physicians in medication management is the failure to insist upon the other treatments which are known to be important for the long-term success of ADHD. The overprescription of stimulant drugs, though undoubtedly magnified by public hysteria and the media, represents a real problem. At the same time, practitioners in schools and clinics often fail to provide physicians with the support they need in terms of feedback regarding the effect of dosage and drug changes both in the home and school setting. This problem represents failure of communication across professional boundaries, failure to develop a *modus vivendi* between professional disciplines, and a lack of rational distribution of assessment and treatment resources. We have the sad fact of teachers referring children for medication because they cannot be managed in the classroom, partly because the school system itself is bogged down in meetings and assessments required by law, with few resources left to address immediate behavioral concerns in the classroom, and partly because school psychologists and other professionals have little training in actual intervention strategies, but have plenty of training in modes of assessment which are both outmoded, time consuming, and inappropriate for the school setting.

Underprescription of stimulants is also a problem. There are many children who go unrecognized as having a legitimate disorder with profound consequences for their own and their family's development. This represents a failure of programs for screening with tools that can identify the threshold for administration of drugs, as well as an inadequate understanding by the public of the importance of early recognition and intervention.

5.19.9.3 Research Issues in ADHD

The current diagnostic criteria are based entirely upon observable symptoms or behaviors directed at the two concepts of overactivity–impulsivity and inattention. Yet there is clear evidence that activity and attention are both multidimensional concepts. Activity that involves motor overflow and fidgeting is quite different from activity that is disrupted because action schemas, both short- and long-term, flounder due to lapses of working memory or lack of meaningful goals. The loss of attention due to lack of arousal is clearly different than that involving a highly aroused, overly vigilant state in which every stimulus has excitatory value and salience. The brain is too complex and subtly geared to the richness of the environmental transactions it must make to have one activity center or attention center, yet our assessments and treatments appear to be predicated on nineteenth-century concepts of the way the brain works. If there are several different circuits involved in alerting to, switching to, and sustaining focus on things, biology dictates that if it can go wrong, at some point it will, for some of the people some of the time. Therefore, we can expect there to be several different types of attention disorder.

As James (1890) so presciently observed, the key to behavioral inhibition is closely related to attention, yet our criteria make no distinction between disinhibition in the classroom due to the inattention of the poor reader faced with an impossible task, and disinhibition which comes from an extremely low threshold for detecting movement in peripheral vision. The major research task, then, in our opinion is the resolution of the heterogeneous syndrome we now call ADHD into subtypes based on a clear understanding of the underlying brain mechanisms which regulate attentional and inhibitory states. Subtypes based solely on overt symptom criteria leave us at a stage of nosology comparable to that when medicine included fever as a major class of disorder. (A fuller discussion of the relationship between neurocognitive models and ADHD is given by Conners et al., 1995.)

5.19.10 SUMMARY

ADHD has evolved from nineteenth-century concepts of impairment of will, to an organically based neurological condition, to a behavioral syndrome of uncertain etiology. Despite limitations in knowledge about the etiology of the condition, considerable agreement regarding the clinical features, developmental course, response to treatment, and adult outcome have accumulated, allowing reasonable preventive, ameliorative, and therapeutic interventions. The core features of inattention and hyperactivity–impulsivity are readily identified using clinical interview, rating scales, and developmental history. The presence of several comorbid symptoms, including conduct disturbance, oppositional behavior, learning disorders, anxiety, and depression, complicates assessment and enlarges the boundaries of treatment needs for most ADHD children beyond the core symptoms themselves. ADHD appears to encompass a spectrum that runs from near-normal to very severe, posing difficult problems of determining a level of functional impairment that warrants diagnosis and intervention. This leads to broad variations in estimates of prevalence. There is still uncertainty as to whether inattention and hyperactivity are part of the same disorder, or two separate disorders. The fact that many different risk factors may lead to ADHD, including genetic, medical, environmental, temperamental, metabolic, and nutritional variables, suggests that ADHD may have several subtypes depending upon the pattern of insults to the developing brain. Protective factors enter in as variables that can reduce impairment below the threshold level of expression required for diagnosis. It is relatively clear that in the absence of intervention and protective factors such as high IQ or good family circumstances, untreated ADHD results in an adult condition of considerable consequence in terms of overall adjustment, vocational and academic accomplishment, and productive lifestyle.

Except for relatively mild versions of ADHD, multimodal treatment is almost always indicated. The sequence, degree, and length of these treatments may vary as a function of developmental level, emergent secondary symptoms such as problems in peer relationships, and parental and community resources. Most treatment packages will include a consideration of medication, school interventions for both behavior and academic competence, and interventions with the parents as the main therapeutic vehicles. Child-based interventions, such as cognitive therapy and psychotherapy, will be less useful, although these can sometimes be quite helpful in individual cases. The use of behaviorally based strategies such as token systems, contracting, and self-monitoring will prove to be more helpful. Pharmacologic management is also a multimodal therapy in the sense that all elements of the social system—school, child, parent, and physician—need to be involved for successful implementation of this adjunct to the total treatment package.

Future research with ADHD will probably focus upon continued efforts to identify the particular nature of the anatomic, neurochemical, and molecular bases of the disorder, with more precise assessment tools being linked to better understanding of the brain-related processes involved. The resolution of ADHD into more specific subtypes, identifiable by behavioral methodologies, would seem to be a particularly important clinical goal. On the treatment side, ongoing studies of the relative merits of single and combined therapies should elucidate which treatment strategies are effective, although such findings will ultimately require developmental level-specific versions to be useful.

5.20.1 INTRODUCTION

The constellation of conduct disorders in children and adolescents presents a major challenge for society. Conduct disorders account for about half of all youth referrals for mental health services, tend to remain stable or worsen over time, and often cross generations (Costello, 1989; Loeber, 1990). Youth exhibiting various forms of conduct disorders victimize others, disrupt their families, fail at school, commit crimes in the community, and abuse alcohol and other drugs. In some cases, conduct disordered behaviors persist throughout the individual's life. These disorders inflict untold psychological, social, and economic costs on youth, families, victims, and communities, in the form of remedial education, law enforcement, heavy utilization of outpatient and inpatient mental health services, physical and emotional harm to others, property destruction, substance abuse, teen parenthood, school dropout, and adult criminality (Robins, 1981).

5.20.2 CONDUCT DISORDERS

5.20.2.1 Phenomenology

Conduct disorders are characterized by a recurring and persistent pattern of antisocial behavior involving the violation of others' basic rights and major societal norms or rules. The term which used to be singular is now plural in recognition of the multiplicity of profiles exhibited by youth with a conduct disorder. Some youth manifest conduct disorder in terms of overt aggressive and hostile acts towards others, while other youth show a pattern of covert, deceitful acts (e.g., stealing, lying, truancy) without accompanying interpersonal aggression, and still others show a combination of these two patterns of antisocial behavior. For some youth, conduct problems begin around school entry, and for others these problems do not emerge until the start of puberty. Conduct disorder can be found in youth with poorly developed relationships with peers and in youth who have well-developed social networks albeit with deviant peers. In sum, although many of these youth have in common some aspects of antisocial functioning, there is considerable variation in terms of expression, age of onset, and social relations.

Developmental context is important in considering whether aggressive or otherwise antisocial behaviors constitute a conduct disorder. It is common for preschool-age children to engage in some behaviors that bear some resemblance to features of conduct disorder. For example, many four-year olds on at least a sporadic basis take things that do not belong to them, lie to get their way, and display tantrum outbursts that include hitting others or destroying property. Engaging in these behaviors occasionally at age four is sufficiently common to be considered a usual aspect of development. The same behaviors at age ten are developmentally out of step with agemates and are more likely to be indicative of the conduct-disorder constellation. Similarly but at the other end of childhood, the developmental norms of adolescence need to be considered. Adolescence is a period of development marked by rebelliousness punctuated by some acting out behavior. Occasional rule or law breaking, such as skipping school or writing graffiti in a public place, is sufficiently commonplace to be considered almost normative developmentally in adolescence. To distinguish between normative misconduct and antisocial disorder, the frequency and seriousness of the behaviors need to be considered. A competing consideration is that conduct problems including serious misdeeds might be increasing among adolescents to the point that such acts are becoming almost normative in frequency (Coie & Jacobs, 1993).

5.20.2.2 Diagnostic Considerations

In the *Diagnostic and statistical manual of mental disorders* (*DSM-IV*; American Psychiatric Association, 1994), Conduct disorder (CD) falls within a larger domain called attention-deficit and disruptive behavior disorders. CD shares this domain with somewhat related diagnoses of oppositional defiant disorder (ODD) and attention-deficit hyperactivity disorder (ADHD). The *DSM-IV* diagnosis of CD requires the presence of three or more manifestations of repeated and persistent antisocial behavior over a 12-month period before age 18, with the behavioral disturbances resulting in significant impairment in social, academic, or job functioning.

Specifically, the three (or more) manifestations of antisocial behavior can be any of 15 criteria that are distributed across four domains: aggression towards people or animals, destruction of property, deceitfulness or theft, and serious violations of rules. Aggression includes bullying or threatening, fighting, use of dangerous weapons, physical cruelty to people or animals, confrontational theft, and coercive sexual activity. Property destruction includes vandalism or firesetting. Deceitfulness or theft includes breaking and entering, lying to obtain goods or favors or to avoid obligations, and nonconfrontive theft. Serious violations of rules includes staying out late even against parental prohibitions (beginning before age 13), running away, and school truancy.

A major departure by *DSM-IV* over previous versions is the specification of two CD types based on age at onset. *DSM-IV* distinguishes between childhood and adolescent onset. Childhood-onset CD begins prior to age 10 and requires at least one of the criterion manifestations of antisocial behavior before that age. Adolescent-onset CD begins in adolescence but also requires that none of the criterion manifestations occurred prior to age 10. The distinction between early vs. later onset is consistent with differing developmental patterns that have emerged in longitudinal and etiological research.

The *ICD-10* classification system (World Health Organization, 1992) also references conduct disorders in children and adolescence but uses an organizing scheme different from that found in *DSM-IV*. The core definition of conduct disorder in the two systems is essentially the same. However, instead of making the distinction between early and later onset, *ICD-10* identifies different subtypes. According to *ICD-10*, CD can be confined to the family context, which means that antisocial and aggressive behavior is confined primarily to interactions with family members. The unsocialized and socialized types of CD, which were present in earlier *DSM* versions, are part of *ICD-10* and distinguish between youth who have seriously disturbed relationships with other children and youth who are well integrated into their peer group. *ICD-10* categorizes ODD as one type of conduct disorder, whereas *DSM-IV* treats ODD as a category distinct from CD. However, both systems define ODD as the presence of markedly defiant, disobedient, and noxious behavior without the more severe aggressive or antisocial acts that violate the law or others' rights. Furthermore, both systems note that ODD is typically seen in children below the age of 9 or 10 and can be a precursor to CD in some children at a young age.

5.20.2.3 Prevalence

Estimates for the prevalence of CD have varied considerably. Costello (1989) reported that CDs affect approximately 5–8% of the general child population. Kazdin's (1995) review of prevalence indicated that the estimated rate of conduct disorders in children aged 4–18 has ranged from 2% to 6%. *DSM-IV* (American Psychiatric Association, 1994) reported that CD rates for youth under age 18 range from 6% to 16% for males and from 2% to 9% for females, although the basis or source of these estimates is not provided.

It is unclear specifically what has accounted for the wide variation in prevalence estimates. The actual obtained rate, however, can be greatly influenced by the threshold criteria for each of the symptom categories. For example, the symptom category pertaining to initiation of physical fights can be stretched or contracted depending on the frequency and intensity one requires for the fighting criterion. Kazdin (1995) noted that adolescents in the general population report very high rates of theft, assault, and vandalism, which implies that prevalence rates of CD diagnosis based on adolescent self-report could be quite high. In other words, the source of diagnostic information could significantly affect estimate of prevalence. The high variation in prevalence estimates could also reflect different time periods and sampling methods. Finally, there is some evidence to suggest that CD is becoming more prevalent in females over time (Loeber, 1990; Viemero, 1992) while not becoming less prevalent in males. Nonetheless, it is clear that CD is a highly prevalent problem that will not go away on its own.

5.20.2.4 Etiology

Much of the etiological work related to CD has focused on the study of risk factors, and to a lesser extent protective factors, that may impinge on the development of antisocial behavior. A number of significant clusters of risk factors have emerged over many years of research via longitudinal and cross-sectional studies. Some of the main categories of risk for CD include temperament, familial factors, school and peer factors, and sociological factors.

Although there is tremendous variability in developmental outcome, toddlers who show difficult temperaments are at heightened risk of developing conduct problems at school entry which might escalate over time (Campbell, 1991; Campbell, Breaux, Ewing, & Szumowski, 1986). Young children who exhibit greater impulsivity, emotional lability, and irritability than their agemates often face adverse environmental reactions if their behavioral style persists through early childhood. Given that most toddlers exhibit occasional outbursts and impatience, useful delineation of this risk factor emphasizes the frequent, chronic, and persistent nature of temperament difficulties.

Temperament difficulties do not typically persist or escalate independent of environmental context. Here is where familial risk factors may operate to potentiate temperamental risk. It is reasonable to hypothesize that parenting difficulties and family adversity exacerbate the adverse impact of child temperament difficulties, and that child temperament difficulties also add to parental and familial stress (Bates, Bayles, Bennett, Ridge, & Brown, 1991; Campbell et al., 1986; Dumas, 1992; Loeber & Stouthamer-Loeber, 1986; Moffitt, 1990; Offord, Boyle, & Racine, 1991). Such a transactional perspective does not preclude the possibility that there are multiple pathways to conduct disorder. For example, at the extreme ends of the spectrum, in children who do not exhibit early temperament difficulties, marked parenting problems such as severe child abuse can still lead to the development of conduct disorder. Conversely, for children showing intense difficulties with early temperament, positive parenting may not be sufficient to prevent the emergence of conduct disorder. However, any adequate etiological model for conduct disorder also must account for what happens to the many children between those two extremes.

A strong body of evidence exists supporting the contention that parenting difficulties during early and middle childhood significantly influence the development of early conduct problems (Patterson, 1982; Patterson, Reid, & Dishion, 1992; Wahler & Dumas, 1987). Relevant parenting dimensions include poor discipline (Farrington & West, 1981; McCord, 1988; Patterson et al., 1992), lack of positive parental response (Loeber & Stouthamer-Loeber, 1986; Wadsworth, 1980), and coercive family process (Patterson, 1982). Other risk factors in the family context, which may disrupt parenting and contribute to risk for CD, include alcohol and illicit drug abuse by caregivers (West & Prinz, 1987), parental social insularity and social disadvantage (Dumas, 1986; Wahler & Dumas, 1987), parental criminality and psychopathology (Offord, 1982; Robins, 1981), and marital discord (Offord & Boyle, 1986; Rutter & Giller, 1983).

Children already showing disruptive and inattentive behaviors in class tend to develop learning difficulties as well (Moffitt, 1990, 1993a, 1993b), which adds to their frustration. Learning difficulties plus the aversive responses from teachers provoked by aggressive and disruptive behaviors help to create negative school experiences that accelerate conduct problems (Campbell, 1991; Hawkins & Lishner, 1987; Hawkins & Weis, 1985; Hirschi, 1969; Walker & Buckley, 1973). Academic difficulties in elementary school and school failure leading to truancy and dropout during adolescence are both potential contributors to the development of serious antisocial behavior (Loeber, 1990). In addition, there is some evidence that certain school environments, such as those that are disorganized with large classes and nonrewarding practices, can exacerbate antisocial behavior (Rutter, Maughan, Mortimore, Ouston, & Smith, 1979; Rutter et al., 1974).

Disturbed relations with peers is another common source of risk, in the form of rejection by mainstream peers followed by attraction to deviant peer groups (Dishion, Patterson, Stoolmiller, & Skinner, 1991; Elliott, Huizinga, & Ageton, 1985; Snyder, Dishion, & Patterson, 1986; West & Farrington, 1977). A common assertion in the literature is that peers exert a strong influence that can promote antisocial behavior including substance abuse (Dishion & Andrews, 1995; Elliott et al., 1985). However, there is some disagreement about whether the peer influence is a primary causal variable or just a concomitant outcome. For example, Block, Block, and Keyes (1988) demonstrated that early family socialization practices exert a more cause influence than peer variables, particularly on substance abuse. On the other hand, adolescent-onset CD seems to be more closely tied to exposure to deviant peer influences than childhood-onset CD (Capaldi & Patterson, 1994).

Another perspective on possible etiological mechanisms derives from a social information processing framework. Specifically, Dodge and others have identified deficiencies in critical social-cognitive skills that are related to aggressive tendencies (Crick & Dodge, 1994; Dodge, 1985; Dodge, Bates, & Pettit, 1990; Dodge, Pettit, McClaskey, & Brown, 1986). Key features include an attributional bias towards presuming hostile intent in others (Dodge & Frame, 1982; Lochman, 1987), failure to attend to relevant social cues (Dodge et al., 1990), low skill level in social problem-solving (Asarnow & Callan, 1985; Lochman, Lampron, & Rabiner, 1989), and a tendency to view aggression as leading to positive outcomes (Perry, Perry, & Rasmussen, 1986; Dodge et al., 1986).

Yet another category of etiological theory about CD derives from a set of approaches inadequately identified as sociological in nature. A number of researchers from different perspectives have recognized that the larger social context, including neighborhood, economic stratum, community, and cultural reference group, has some connection to the development and desistance of antisocial patterns of behavior in children and adolescents. For example, social interactionists such as Patterson, Wahler, and their colleagues have demonstrated how high levels of family adversity associated with economic disadvantage exert indirect effects on youth antisocial behavior via disrupted parenting and related consequences (Capaldi & Patterson, 1994; Wahler & Hann, 1987). Others have shown how community and peer influences coalesce to impact youth behavior (Sampson & Groves, 1989), how exposure to community violence can increase youth antisocial behavior and other adjustment problems (Richters & Martinez, 1993), and how forces of prejudice and racism manifesting in exclusion from the mainstream, threats to self-identity, and demoralizing conditions of hopeless poverty can induce expressions of anger and outrage taking the form of antisocial acts (Boyd-Franklin, 1989; McLoyd, 1990; Ogbu, 1988).

5.20.2.5 Developmental Course

For childhood-onset CD, children who ultimately develop the disorder show prodromal signs at school entry or even earlier. The early starters often exhibit pronounced cross-situational aggressive behavior between ages four and eight (Dumas, 1992; Loeber, 1988, 1990; Loeber & LeBlanc, 1990; Patterson, DeBaryshe, & Ramsey, 1989), which is quite likely to meet the criteria for a diagnosis of ODD. Early aggression is predictive not only of later delinquency (Loeber, 1990) but also subsequent substance abuse (Hawkins, Catalano, & Miller, 1992). Oppositional-aggressive behavior interacts with parenting difficulties to place such children at further risk as they enter school (Patterson et al., 1992). During the early years of elementary school, children at risk for early-onset CD experience learning difficulties (Offord & Waters, 1983; Rutter & Giller, 1983), particularly in reading and language-related skills (Moffitt, 1993a, 1993b). Such children often engage in high rates of inappropriate classroom behavior that includes ignoring teacher instructions, hitting classmates, disrupting class, and destroying property (Prinz, Connor, & Wilson, 1981). Aversive reactions from teachers (Campbell, 1991; Walker & Buckley, 1973) and rejection from peers (Bierman, 1986; Cantrell & Prinz, 1985; Dodge, 1989; Parker & Asher, 1987) often further escalate the children's conduct problems and set the stage for full-blown CD.

Adolescent-onset CD has a somewhat different developmental course. Unlike youth with childhood-onset CD, the late starters develop at least minimal social skills and adequate peer relations, do not show antisocial behavior problems in early elementary school, and seem to acquire delinquent tendencies more from a deviant peer group than from coercive family interactions (Patterson et al., 1989, 1992). Late starters are not necessarily free from family problems, and their antisocial behavior can precipitate family difficulties (or aggravate existing ones). It is presumed that in comparison with early starters, late starters are more likely to desist by early adulthood with respect to delinquent behavior (Patterson et al., 1992).

5.20.3 CONCEPTUALIZATION AND CLINICAL FORMULATION

5.20.3.1 Multimodal Assessment

Appraisal of core CD symptomatology is a significant facet of assessment. For younger children, the main sources of information about conduct problems are parents and teachers via behavioral rating scales. Direct observation of child behavior in social settings (e.g., home, classroom, playground) can also provide useful data about interactive style, particularly with respect to interpersonal aggression. Structured diagnostic interviews of the caregiver have potential utility with younger and older children. For older children, youth report via self-report instruments (behavioral rating scales, behavioral incident checklists) and structured diagnostic interviews add breadth to the assessment of conduct problems.

Several rating scales have acceptable psychometric properties and adequate coverage of content pertinent to conduct disorder. The Child Behavior Checklist, a 113-item instrument, covers youth ranging from 2–16 years of age and has versions for parent, teacher, and youth report (Achenbach & Edelbrock, 1983). The Conners Parent and Teacher Rating Scales are a collection of instruments varying in length and specificity which are particularly useful for assessing comorbid ADHD as well as nuances of conduct problems and antisocial behavior (Conners, 1969, 1970, 1973; Goyette, Conners, & Ulrich, 1978). The Eyberg Child Behavior Inventory, a 36-item instrument designed specifically to assess aspects of conduct and oppositional problems in youth aged 2–16 years, is particularly useful for pinpointing problem areas and assessing treatment effects (Eyberg, 1992; Eyberg & Robinson, 1983; Eyberg & Ross, 1978).

Some intervention programs rely on direct observation, either in the home or in a clinic analogue setting, as a basis for characterizing the specific nature of the problems and for driving treatment implementation (Patterson, 1982; Sanders, Dadds, & Bor, 1989). With younger children, such observations may involve family tasks that involve free play by children and transition tasks that place demands on them. With older children, the observation tasks tend to take the form of problem-discussion tasks for families to attempt. In general, observation seems to be particularly useful for assessing key family processes and other interpersonal interactions (e.g., playground interactions) that might bear on the maintenance of CD, rather than for trying to establish rates and extent of conduct problems.

A major challenge in assessing conduct problems is the variability in types of symptoms that youth with CD can exhibit. While most of the younger children early-onset CD group exhibit demonstrative aggression towards others in public settings, the older youth are more variable. Some adolescents who clearly qualify for a CD diagnosis exhibit little or no overt aggression towards others but instead commit covert acts such as vandalism, cruelty to animals, or nonconfrontational theft. Others only commit aggressive acts in specific circumstances, such as in coercive sexual encounters. The implication of this variability is that there is no single constellation of symptoms to monitor for all youth with CD.

5.20.3.2 Treatment Formulation

Treatment strategies for CD differ somewhat for pre-adolescents vs. adolescents, and the distinction is not simply between early-onset vs. later-onset CD. By definition, pre-adolescent children exhibiting CD symptomatology belong to the early-onset group. However, adolescents in treatment for CD may have either early-onset or later-onset histories but this difference may not manifest in behavioral differences during adolescence. Consequently, CD treatment for CD may vary as a function of severity and setting constraints rather than onset history.

Historically, treatment for CD focused on intrapsychic approaches including play therapy and individual psychotherapy with children, which have met with less recent acceptance in the absence of evidence for efficacy or promise (Kazdin, 1987). Current treatment focuses much more on the social contexts in which children misbehave, namely in the family, in school, and with peers. Much of the current treatment for CD is predicated on the assumption that children with conduct problems need a concentrated regimen of accelerated positive socialization. Treatment strategies emanating from this assumption enlist parents, teachers, and even peers as therapeutic agents. Essentially, the more ecologically oriented interventions attempt to restructure the youth's social environment to shape and reinforce positive behaviors and limit antisocial behavior.

An alternative formulation focuses on the internal cognitive set characteristic of youth who engage in high rates of antisocial behavior. The proponents of the cognitive approach argue that changes in the social environment, in the absence of addressing beliefs and attitudes that lead to antisocial behavior, will not produce lasting positive gains.

5.20.4 TREATMENT

5.20.4.1 Psychosocial Treatments

One of the most common and well-researched psychosocial treatments for pre-adolescent youth with CD is parent training in behavioral management skills. Although there are several variants of parent training (Miller & Prinz, 1990), most approaches have in common a core set of principles and goals: (i) Parent trainers help parents pinpoint, and then monitor, specific positive and negative behaviors that they want to change. (ii) Positive reinforcement, which is a central construct in parent training, is emphasized as more important than punishment. (iii) Parents are encouraged to replace corporal punishment with time-out from reinforcement for the younger children or loss of privileges for the older ones. (iv) The principle of shaping is promoted as a strategy for starting with children's existing behavioral repertoires and expanding their capabilities. (v) Systematic attending and ignoring are key parenting skills that are particularly effective with younger children. (vi) Many of the parent training programs emphasize positive communications by parents to motivate children and strengthen family relationships. (vii) Programs attempt to increase the probability of positive parental attention for child prosocial behaviors (e.g., cooperation, calm talking, appropriate play behavior, sharing, complying with adult requests, staying out of fights) and to assist parents in coping more effectively with child antisocial, aggressive, and noncompliant behaviors.

Parent training is administered in group or individual format (or some combination of both). There are advantages and disadvantages to each format. With the group approach, parents receive support and modeling from other parents, they get to benefit from hearing other parents' questions and the group leader's responses, and the process is more cost efficient. Disadvantages of the group format include: (i) a fixed program that does not permit individual variation in content or pacing, (ii) fewer opportunities to handle each parent's concerns and difficulties, and (iii) inflexibility with respect to scheduling (or rescheduling). The individual format (i.e., therapist works with one family at a time) has a number of advantages: (i) a functional analysis of the particular family can be conducted; (ii) the pace, content, and relative emphasis in therapy can be tailored to the family's needs; (iii) crises can be handled more readily; and (iv) the therapist develops a closer relationship with youth and family that can sustain engagement in treatment. Conversely, therapy with individual families does not engender the same level of social support and normalizing of experiences that the group approach affords.

With adolescents, family-based treatment approaches tend to take the form of family therapy over parent training, with some exceptions (see Patterson, Chamberlain, & Reid, 1982). In contrast to parent training in which the therapist works primarily with the parents, family therapy involves at least the parent(s) and adolescent plus other members of the household such as siblings and extended family. Some of the more prominent family therapy approaches include structural family therapy (Minuchin, 1974; Minuchin & Fishman, 1982; Minuchin, Montalvo, Guerney, Rosman, & Schumer, 1967), functional family therapy (Alexander & Parsons, 1982; Barton & Alexander, 1981; Jameson & Alexander, 1994), and behavioral family therapy (Miller & Prinz, 1990; Tolan & Mitchell, 1989). Although adopting somewhat varied tactics, these three therapy approaches share in common the recognition that youth antisocial behavior is bound up to some degree in family interactions. Furthermore, these approaches all attempt to help families attain their goals and improve relationships and communication within the family.

A relatively new treatment approach has emerged called "multisystemic therapy," which is a hybrid of traditional family therapy and behavior therapy with a strong emphasis on ecological context (Henggeler & Borduin, 1990).

In multisystemic therapy, the therapist works with the family and the youth in the home and elsewhere to alter systemic processes known to be related to antisocial behavior. Multisystemic therapists address parental discipline, family communication and affect, peer associations, school issues, and other potentially significant domains in the larger contexts in which the youth operates.

In addition to interventions that focus primarily on larger contexts such as school and home, there are also youth-focused approaches that involve therapists working one-on-one or in small groups with children or adolescents. The youth-focused approaches arise primarily out of the social-skills and cognitive-behavioral areas (Dush, Hirt, & Schroeder, 1989; Kazdin, 1987; Michelson, 1987). Youth-focused treatments for CD include social skills training, problem-solving training, self-control training, anger management, or some combination of these. Social-skills approaches typically include individual and group reinforcement, coaching and shaping of specific interpersonal behaviors, positive group activities, friendship skills, and listening/speaking skills (Bierman, 1989; Bierman, Miller, & Staub, 1987; Michelson, Sugai, Wood, & Kazdin, 1983; Prinz, Blechman, & Dumas, 1994). Other approaches have combined interpersonal problem-solving and self-instruction (self-talk) in an effort to alter the cognitive bases assumed to underlie conduct problems (e.g., Kazdin, Bass, Siegel, & Thomas, 1989; Kazdin, Esveldt-Dawson, French, & Unis, 1987). Lochman and colleagues have focused on a cognitive-behavioral variant, primarily with young adolescents, that has focused on strategies for anger management (Lochman, 1992; Lochman, Burch, Curry, & Lampron, 1984; Lochman & Curry, 1986).

5.20.4.2 Pharmacological Treatments

Several psychoactive medications have been tried with children or adults who exhibit various forms of aggressive behavior. For example: (i) methylphenidate, D-amphetamine, pemoline citrate, and clonidine have been used with youth with comorbid CD and ADHD (Hinshaw, 1991; Hinshaw, Heller, & McHale, 1992); (i) diphenhydramine, clonazepam, and buspirone have been used with children showing CD combined with anxiety; (iii) fluoxetine, imipramine, desipramine, nortriptyline, and bupropion have been used for comorbid CD and depression; and (iv) lithium carbonate, neuroleptics, propranolol, carbamazepine, antidepressants, and buspirone have been used to address aggressive symptomatology (including self-injurious behavior) in individuals with CD (Campbell & Spencer, 1988; Zavodnick, 1994). However, evidence has not yet emerged in support of pharmacological treatment for the general population of youth with conduct disorder (Stewart, Myers, Burket, & Lyles, 1990). Zavodnick recommends medication primarily as an adjunct to behavioral and parent management treatments, particularly when conduct disorder co-occurs with a diagnosable disorder such as ADHD or depression.

CD and associated problems such as substance abuse, criminality, risky sexual behavior, and school failure are complex constellations of behaviors that are embedded in social contexts. Pharmacological treatment is predicated on an assumption of biological determination (or at least biological influence) that runs orthogonal to a social-contextual analysis. It is not clear at the present time that pharmacological treatment should be the primary approach of choice for many youth whose patterns of antisocial behavior are extricably connected to family, peer, school, and community influences.

5.20.4.3 Efficacy/Effectiveness of Treatments

Social-learning-based parent training for families with a conduct-problem child or young adolescent has met with some success by focusing on parental monitoring and supervision, discipline (e.g., compliance training, timeout, elimination of coercive parenting methods), and quality of parent–child interaction (Dumas, 1989; Kazdin, 1987; Miller & Prinz, 1990). A number of studies conducted by Patterson and colleagues have demonstrated that the majority of children exhibiting pronounced aggressive behavior and related conduct problems respond favorably to systematic parent training interventions (Fleischman, 1981; Patterson, 1974, 1982; Patterson, Chamberlain, & Reid, 1982; Patterson & Fleischman, 1979). Webster-Stratton and her colleagues also found that parenting training, primarily in group-administered formats, produced significant gains for conduct problems in preadolescents over untreated controls that were maintained at one-year follow-up (Webster-Stratton, 1984; Webster-Stratton, Hollinsworth, & Kolpacoff, 1989; Webster-Stratton, Kolpacoff, & Hollinsworth, 1988).

Parent-training investigators have acknowledged that optimum results are not always obtained and that there are obstacles to intervention (Hawkins, Catalano, Morrison, et al., 1992; Kazdin, 1987; Miller & Prinz, 1990).

One challenge is the difficulty in producing lasting changes in families with severe socioeconomic disadvantage and social isolation (Dumas, 1984; Dumas & Wahler, 1983; Patterson & Fleischman, 1979). Another problem is keeping families in treatment without premature attrition, or for that matter getting families into treatment to begin with (McMahon, Forehand, Griest, & Wells, 1981; Miller & Prinz, 1990; Prinz & Miller, 1994). In view of these kinds of difficulties, there is growing support for home-based family interventions (Fraser, Pecora, & Haapala, 1991; Henggeler, Melton, & Smith, 1992; Tharp, 1991) as a way of addressing the needs of culturally and economically diverse populations, avoiding the perceived stigma of clinic-administered treatments, and overcoming the practical obstacles of transportation, childcare, and management of appointments.

Multisystemic therapy (MST; Henggeler & Borduin, 1990) has shown promise with youthful offenders, a most challenging population. Henggeler et al. (1986) compared MST with usual community treatment for juvenile offenders and their families and found that MST was associated with a decrease in reported conduct and related adjustment problems and an improvement in quality of family interaction. Mann, Borduin, Henggeler, and Blaske (1990) randomly assigned chronic juvenile offenders either to MST or individual counseling and found that the youth participating in MST showed significantly lower recidivism over a four-year period (22% vs. 71%). Similar results were reported by Borduin, Henggeler, Blaske, and Stein (1990) in a study applying MST to adolescent sexual offenders. Henggeler, Melton, and Smith (1992) found that MST proved superior to incarceration with respect to subsequent behavior of serious juvenile offenders.

Child cognitive-behavioral therapies have led to at least short-term benefits in observed classroom behavior, academic performance, and teacher/parent reports of aggression and social adjustment (Dush, Hirt, & Schroeder, 1989). Two notable studies targeted truly antisocial samples and evaluated long-term impact (Kazdin, Bass, Siegel, & Thomas, 1989; Lochman, 1992). Kazdin et al. (1989) found that interpersonal problem-solving led to major improvements (immediate and at one-year follow-up) in prosocial behavior and in reductions of aggressive behavior at home and school but cautioned that child-focused intervention may not be sufficient for sustained, clinically significant improvement. Lochman (1992) found that a school-based cognitive-behavioral intervention had significant effects at three-year follow-up in terms lower rates of substance use (alcohol and marijuana) and higher rates of self-esteem in mid-adolescence, compared with untreated peers. However, the intervention had only limited effects on the adolescents' general level of conduct problems, causing Lochman (1992) to suggest that family intervention may be crucial to use in combination with youth-focused interventions.

Social skills interventions have also shown some degree of promise. Michelson et al. (1983) found that a social-skills training program with children aged 8–12 years who had conduct problems produced one-year maintenance of improved social adjustment. Bierman (Bierman, 1989; Bierman, Miller, & Staub, 1987) tested a 10 session social skills training with aggressive-rejected children aged 7–10 years using heterogeneous training groups composed of high-risk and competent children, individual and group reinforcement, coaching and shaping of specific interpersonal behaviors, and enjoyable group activities. Bierman et al. (1987) reported a reduction in antisocial behavior and some improvement in peer acceptance at one-year follow-up. Prinz et al. (1994) evaluated a peer coping-skills intervention that focused on enhancing speaking and listening skills for handling social challenges in small heterogeneous groups (i.e., equal proportions of children with high-risk and socially competent status in the same group). Children aged 7–9 years with high rates of aggressive behavior who received the peer coping-skills program made significant improvement over controls at post-intervention and next-school-year follow-up in terms of a reduced level of aggressive behavior and greater communication effectiveness as judged by teachers (Prinz et al., 1994). Of additional interest is that inclusion of socially competent children without aggressive profiles did not result in iatrogenic effects on those children and actually produced significant gains in communication effectiveness (over socially competent children who did not receive the peer intervention).

5.20.5 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

From a treatment perspective, one of the most challenging aspects of conduct disorder work has to do with engaging youth and families in the treatment process and maintaining engagement and full participation. Youth with antisocial behavior problems tend to come from families where many of the adults in the household are antisocial themselves and somewhat reticent to participating in treatment. Motivating caregivers to participate meaningfully in the treatment process is as yet an unsolved problem. In a free society, we cannot realistically force youth or parents to participate in treatment. The challenge is to find strategies for motivating and supporting prosocial treatment participation.

A related issue concerns matching of interventions and treatment strategies with particular youth and families. Although subgroups of youth with conduct disorder have been identified, these subgroups are not sufficiently specific or useful to match with treatment strategies. Treatment for conduct disorders often fails, and there are many contributing factors to such failure that need to be studied in order to arrive at clusters of characteristics and circumstances under which one strategy might be more successful than another. Cultural, familial, developmental, and topographical (i.e., type of conduct problems) variables may all play a role.

The future treatment strategies for conduct disorders that have the greatest likelihood for success will probably look like this. (i) Multiple participants, including parents, siblings, teachers, peers, and targeted youth, will contribute to the breadth of interventions. (ii) Interventions will begin early in the trajectory of antisocial behavior. (iii) Greater emphasis will be placed on preventive interventions before children enter the judicial system or are expelled from school. (iv) Interventions will be longer (sometimes lasting for several years), with phases of periodic maintenance and booster contacts. (v) Service delivery systems will rely more heavily on ecologically oriented models that include home visits, neighborhood programs, and family-support approaches.

5.20.6 SUMMARY

The conduct disorders are characterized by a recurring and persistent pattern of antisocial behavior and violation of major societal norms. Antisocial behaviors typically fall into four domains: aggression towards others, destruction of property, theft and other deceit, and serious rule violations (e.g., chronic school truancy). *DSM-IV* distinguishes between childhood and adolescent onset of conduct disorder. Childhood-onset conduct disorder that persists throughout adolescence is associated with greater severity and long-term adverse consequences (e.g., adult criminality, higher rate of violence) than is found with adolescent-onset conduct disorder. Etiological factors include parenting difficulties during early and middle childhood, other familial factors, early temperamental difficulties, school effects, and disturbed peer relations. Assessment methods for conduct disorder include direct observation with younger children, diagnostic interview schedules with youth or caregivers, and rating scales with parent, teacher, or youth informants. The more promising treatment approaches include social-learning-based approaches to parent training and family intervention, an ecological family approach called multisystemic therapy, and child cognitive-behavioral therapies that include social skills interventions, interpersonal problem-solving, and cognitive attributional retraining. Psychopharmacological intervention may be helpful primarily as an adjunctive treatment for youth who have comorbid ADHD or depression. Future research will need to address the challenge of motivating youth and families in treatment and in developing better strategies for matching approaches and incentives to individual cases.

5.21.5 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE 557

5.21.6 SUMMARY 559

5.21.7 REFERENCES 559

5.21.1 INTRODUCTION

Only a half century ago the use of alcohol and other drugs among adolescents was quite rare, with the number of youth reporting ever drinking or using drugs estimated at one in five and frequent drinking or drug use essentially nonexistent (McCarthy & Douglass, 1949; Prosser, 1954). Over the years drinking and drug use have escalated sharply, to proportions many consider epidemic (Johnston, O'Malley, & Bachman, 1993). Similar increases in problems associated with alcohol and other illicit drug use have also been observed, including premature school drop out, crime, injuries and fatalities due to accidents and violence, sexual promiscuity and risk for sexually transmitted diseases, and teen pregnancy.

Although substance use and related problems have received greater attention in mental health fields in recent years, researchers and clinicians continue to struggle with fundamental conceptual and empirical issues. Some of the most perplexing issues include the complex and varied factors influencing the development of the disorders, the heterogeneous presentation of substance abuse disorders, the similarities and differences between adolescent and adult abuse, and the comorbidity of substance abuse with other disorders among adolescents, complicating diagnosis, assessment, and treatment.

This chapter provides an overview of adolescent substance abuse disorders, highlighting the challenges facing researchers and clinicians. The chapter is divided into three main sections focusing on (i) the nature of substance abuse disorders, (ii) methods for assessing adolescent substance use, and (iii) intervention approaches employed and the evidence for treatment effectiveness. Recommendations for further study of adolescent substance abuse disorders are also presented.

5.21.2 SUBSTANCE ABUSE DISORDERS

5.21.2.1 Phenomenology

Considerable ambiguity exists regarding the definition of substance abuse. A major obstacle in defining the concept of abuse is the array of terms such as recreational, experimental, problematic, pathological, risky, harmful, occasional, episodic, regular, light, moderate, and heavy use, employed to characterize substance use (Kaminer, 1994). On one point, however, theorists generally agree: substance abuse is not a unitary concept, but a complex phenomenon with heterogenous patterning and multiple determinants.

A unique characteristic of substance abuse disorders, unlike other mental disorders, is that they vary depending on factors such as the immediate social environment or the availability of substances. Moreover, classification depends on the presence of a "willing host [the abuser] who is an active participant in generating these disorders" (Newcomb, 1995, p. 7). Yet, substance use is a covert behavior not easily seen by parents, teachers, or other health professionals whose suspicion of use can be low. Failure to detect signs of use, in the absence of valid, reliable, practical definitions for the disorders, contributes to substance abuse being a commonly missed or misdiagnosed problem and hampers clinical efforts to identify adolescents in need of assessment, preventive care, and treatment. In addition, these problems have probably slowed research effort on prevalence, history, genetics, and treatment outcome (Bukstein, 1995).

5.21.2.1.1 Problems in defining abuse

The peak reporting of substance use occurred at the end of the 1970s and early 1980s when as many as 90% of high school seniors reported some alcohol use and nearly 50% marijuana use. Moreover, the majority of substance-involved youth do not develop substance abuse problems and do not go on to abuse as adults, with most drug use dropping sharply after age 21 (Blane, 1976; Kandel & Logan, 1984). In light of high rates of involvement, together with evidence for the discontinuity of use from youth into adulthood, the reality of normative adolescent substance use cannot be ignored. Some researchers have even suggested that, to a degree, drug use has developmental, adaptational utility for adolescents (Labouvie, 1986; Shedler & Block, 1990). Adolescents may use alcohol and other drugs to assert independence from their parents, identify with peers, or oppose societal norms and values, all part of the normal exploration of identity issues.

At the other extreme, any level of substance use by adolescents could be considered pathological. Use, or even possession, of alcohol and other drugs by underage youth constitutes illegal behavior in the USA and is often accompanied by truancy, curfew violations, shoplifting, and a host of other problem behaviors (Donovan & Jessor, 1985). Substance use also increases exposure to risky situations such as driving while intoxicated, engaging in sexual behavior that increases risk for AIDS, and engaging in violent exchanges (Farrell, Danish, & Howard, 1992; FeCaces, Stinson, & Hartford, 1991). Further, substance use can interfere with crucial developmental tasks, such as prosocial identity formation, interpersonal and educational skill acquisition, and family and work responsibility assumption (Baumrind, 1985; Bentler, 1992).

Certainly, diagnosing the vast majority of teenagers with a substance abuse disorder is problematic and a definition by which to identify adolescents abusing substances and in need of treatment is critical. Baumrind (1985) argued that drug abuse should be defined empirically, using frequency and problem consequences as determinants. Similarly, Pandina (1986) offered an operational definition on the basis of intensity (quantity and/or frequency) of use, presence of criteria-based symptoms, and negative consequences. However, no clear cut-offs have been established for quantity and frequency. The substance-related symptoms exhibited by adolescents have rarely been the focus of investigation and, as a result, are still poorly understood (Blum, 1987; Filstead, Parrella, & Conlin, 1988; Stewart & Brown, 1995). And even when a pattern of negative consequences is present, whether they result from substance use or stem from other preexisting or cooccurring factors such as another psychiatric disorder is often unclear (Bukstein, 1995).

Some have argued that substance abuse reflects only one aspect of a syndrome of problem behavior (Jessor & Jessor, 1977) or of general deviance (McGee & Newcomb, 1992). From such a perspective, substance abuse is not conceptualized as a disorder, but as a cluster of norm-violating attitudes and activities such as unconventionality, criminal behavior, and low academic orientation (Donovan & Jessor, 1985; McGee & Newcomb, 1992). Thus, a definition of substance abuse may need to address the broader context of problems intrinsically related to drug and alcohol use.

The widely varied patterning of use among adolescents must also be taken into account in any definition of substance abuse. Types of drugs used should certainly be considered. Alcohol, marijuana, stimulants, cocaine, opioids, sedatives, hallucinogenics, inhalants, and even anabolic steroids (for athletic enhancement) are all potential agents of abuse with specific pharmacologic effects. In addition, the number of drugs used and the combinations of drugs, age of the user, quantity and frequency of use of each substance, negative consequences stemming from use, presence of related problems, and developmental progression of use may all be factors that bear on the distinction between nonproblem use and abuse.

Tolerance, for example, develops rapidly to the euphoric effects of stimulants. With the larger doses of stimulants necessary to reproduce the euphoria, the potential for negative side effects increases and toxic overdose can be fatal. By contrast, tolerance develops more slowly to alcohol and the toxicity of marijuana is generally low. Thus, a consumption of one or two beers or smoking marijuana with friends on the weekend might not be considered abuse for a 17-year-old high school senior, whereas snorting crystal methadrine (i.e., crack) at the same rate might be judged more serious. On the other hand, an 11-year-old drinking one or two drinks or smoking marijuana with any regularity would probably be considered for treatment of substance abuse, given the quantity/frequency of use at such an early age of onset and the potential for rapid developmental progression of drug use.

5.21.2.1.2 Adult vs. adolescent use

Although most conceptualizations of adolescent abuse have been based on adult theories, models, and findings, the appropriateness of this approach has long been questioned and evidence is accumulating that adolescent use differs from adult use in important ways. Some differences are probably due to the restricted age range of the adolescent period. Adolescents have typically been experiencing substance problems for a shorter length of time (Brown, Mott, & Myers, 1990) and have had less time to exhibit deterioration in role functioning (Blum, 1987). Compared to adults, adolescents have also encountered fewer and different serious consequences related to their use, including physical evidence of dependence (Filstead, 1982; Filstead et al., 1988; Vingilis & Smart, 1981).

The patterning of use also appears to differ for adults and adolescents. For example, White and Labouvie (1989) found that adolescents drink less frequently than adults and consume less alcohol overall, but consume larger amounts at one time. Given the smaller body size and weaker tolerance of many youth, teens who drink can experience dangerous physical effects and alcohol-related problems at a lower level of consumption than adults. Brown et al. (1990) reported that 70–98% of adolescents in treatment abuse multiple substances, whereas reports of adult polysubstance use have been considerably lower. Also, the types and patterns of withdrawal symptoms among adolescents appear unique (Brown, Vik, & Creamer, 1989; Martin, Kaczynski, Maisto, Bukstein, & Moss, in press; Stewart & Brown, 1995). Adolescents also have a higher likelihood of certain negative social consequences, given their position of dependence and lower status in family and social systems (Barnes, 1984; White & Labouvie, 1989).

However, researchers have also noted similarities between adolescents and adults with respect to the pharmacologic effects of drugs, reasons for use, and the settings in which use occurs (Barnes, 1981). Also, similarities have been found with respect to patterns of problem drinking, including psychological dependence, binge drinking, and social consequences of drinking (Andersson & Magnusson, 1988; Hughes, Power, & Francis, 1992).

The question of whether adolescent abuse is a distinct category from adult abuse may be intertwined with the issues of nonproblem use versus abuse. Some researchers have found greater continuity from the adolescent period into adulthood for particular typologies of early-onset problem drinking (Babor et al., 1992). However, the majority of adolescents do not fit the severe category. All along the continuum of quantity/frequency and negative consequences of use there are adolescents who still appear to "mature out" of problem use when they reach adulthood (Blum, 1987; Winters & Henly, 1988). As evidence accumulates, we may yet be able to identify different levels or forms of use among adolescents, such as nonproblem use, problem use with relatively good prognosis for spontaneous remission, and problem use that persists into adulthood.

5.21.2.1.3 Comorbidity

Substance abuse disorders in adolescents are widely held to have a high prevalence of comorbidity with other psychological disorders. The most common disorder coexisting with adolescent substance involvement is conduct disorder. DeMilio (1989) found that 42% of adolescents presenting for treatment of substance abuse also met criteria for conduct disorder; Bukstein, Glancy, and Kaminer (1992) found 62% of adolescents receiving inpatient treatment were dually diagnosed. The interactive effects of conduct disorder and substance use and abuse are not well understood, but evidence indicates that dual diagnosis increases the likelihood of continued behavioral disturbance and substance use. Although attention deficit hyperactivity disorder (ADHD) has been hypothesized as a comorbid condition, Alterman and Tarter (1986) concluded that the apparent relationship between substance abuse and ADHD was an artifact of the high coincidence of ADHD and conduct disorder. This finding has been confirmed by Barkley and his colleagues who found that adolescents with only ADHD used substances no more frequently than normals (Barkley, Fischer, Edelbrock, & Smallish, 1990).

Affective disorders, anxiety, and bulimia also commonly coexist with adolescent substance abuse. For example, DeMilio (1989) reported a dual diagnosis of major depressive disorder for 35% of a treatment sample; Bukstein et al. (1992) found 30% in an inpatient setting. Studies examining the coexistence of anxiety and other disorders with substance abuse have been more common with adults but, like depression, the pattern of the relationship is probably similar for adolescents. Possible mechanisms for the connection between mood and substance abuse disorders are the depressive pharmacological effects of some drugs and the negative social consequences, such as school failure and peer rejection, experienced by adolescents using alcohol and other drugs. Similarly, the actual or expected pharmacologic effects of substances in reducing anxiety is an obvious explanation for the comorbidity with anxiety disorders. The relationship between substance abuse and bulimia is less clear, and the high comorbidity between bulimia and mood disorders may account for some of the comorbidity between bulimia and substance abuse.

The comorbidity issue adds a level of complexity to understanding substance abuse. Research examining adolescent substance abuse disorders often specifically excludes adolescents with dual diagnoses in order to limit potential confounds. However, even when the coexistence of disorders is the question of interest, the lack of valid, reliable definitions of substance abuse and other disorders of childhood and adolescence has hampered investigations. Moreover, the concept of comorbidity is inherently fraught with problems such as identifying comorbid disorders using sets of symptoms which result from the same underlying cause. For example, Crowley and Riggs (1995) observed that adolescents dually diagnosed with substance abuse and conduct disorders epitomize the general deviance syndrome, in which substance use and other deviant behaviors are viewed as stemming from common causes. Whether substance abuse is primary or occurs secondary to another disorder, and how the interaction of coexisting disorders influence the onset, identification, course, and treatment of substance abuse, problems remain in question.

5.21.2.2 Diagnostic Features

Formal diagnostic classification systems for substance use disorders have primarily evolved since the mid-1970s and have been developed exclusively for adults, with no distinction made between adolescent and adult users. The first criteria-based classifications appeared in the third edition of the *Diagnostic and statistical manual of mental disorders* (*DSM-III*; American Psychiatric Association, 1980), which identified two categories of substance use disorders: substance abuse and substance dependence. Substance abuse was defined as pathological use associated with impairment of social or occupational functioning with a one-month duration, and dependence as the presence of tolerance or withdrawal and either pathological use or impairment in social or occupational functioning due to such use. Prior to the third edition, the *DSM* viewed substance use problems such as alcoholism and drug dependence as subsets of sociopathic personality disturbance. The designation of a separate category for substance use disorders in *DSM-III* differentiated substance use from antisocial behavior more generally and recognized the importance of research on the nature of the disorders (Nathan, 1991).

A number of serious limitations of *DSM-III* were noted, however, including the insensitivity of the criteria in addressing heterogeneity of problems, the lack of theoretical and empirical basis for some criteria, and inconsistencies across criteria in various substance categories (cf. Nathan, 1991; Rounsaville, 1987). In addition, the reliance on tolerance or withdrawal for the dependence diagnosis determined that, in most cases, adolescents could only be diagnosed as abusers, since they rarely exhibit many of the tolerance or withdrawal symptoms for alcohol or other drugs (Hughes et al., 1992; Vingilis & Smart, 1981).

The *DSM-III-R* (American Psychiatric Association, 1987) was designed to correspond more closely to the *International classification of disease, ninth edition* (*ICD-9*), which had effected a conceptual shift in classifying substance use disorders. In keeping with the conceptual shift, the definition of dependence was expanded to include clinically significant behaviors, cognitions, and symptoms indicative of use and no single symptom was required for a diagnosis of dependence. Marked tolerance and withdrawal symptoms remained in the list of criteria, but other criteria—such as spending large amounts of time on activities to acquire substances, symptoms of intoxication when expected to fulfill major role obligations at work, school, or home, and giving up important activities because of substance use—made it easier for adolescents to be diagnosed with dependence. The changes also allowed for more variability in patterns of use.

By default, abuse was diagnosed when sufficient criteria for dependence were not met. Thus, abuse was conceptualized as a milder or predependence stage in the cluster of disorders. However, some research suggests that abuse and dependence disorders have distinct courses (Hasin, Grant, & Endicott, 1990), questioning the notion of a presumed continuum of severity.

The revision of the system for *DSM-IV* (American Psychiatric Association, 1994) was intended to reflect empirical research more closely and to increase compatibility with the *ICD-10* system. Accordingly, three essential changes were made to the classification of dependence: the criteria regarding the inability to fulfill major role obligations and the criteria for duration were dropped, and subtypes of tolerance and withdrawal symptoms were added. However, adolescents with substance use problems commonly experience difficulty in meeting role obligations. With regard to educational expectations, truancy, attending classes while under the influence of alcohol or drugs, school failure, and premature dropout are common. Similarly, failures to meet role obligations are frequently observed in family contexts. Thus, the elimination of the role obligation criterion will probably reduce the number of adolescents who are diagnosed as dependent.

The criteria for substance abuse in *DSM-IV* were expanded, requiring the presence of clinically significant impairment or distress, including the failure to fulfill major role obligations and recurrent substance-related legal problems, as part of the maladaptive pattern of substance use. The addition of the role obligation criteria to this category could facilitate diagnostic classification. Nevertheless, adolescents who show a maladaptive pattern of use must now also exhibit at least minimal impairment or distress. This moves classification of abuse away from a topographical definition of substance use, such as quantity, frequency, or patterning of use, toward a definition based on dysfunction associated with use, and essentially raises the bar for adolescents to meet criteria, since adolescent behaviors tend to be more detectable than distress resulting from the behaviors.

The most disturbing aspect of the evolution of classification systems for substance use is the complete lack of evidence either to support or reject the applicability of the systems with adolescents. To illustrate, consider the nature of the prevailing diagnostic systems. The *DSM* and *ICD* systems are categorical rather than dimensional, classifying substance abuse on the basis of clustering of symptoms as opposed to viewing symptoms as occurring along a continuum. Within these systems, then, it is possible for adolescents to exhibit high quantity and frequency of use, yet not meet criteria for a substance abuse disorder if they manage to avoid negative consequences or other signs of impairment considered part of the discrete cluster of symptoms that currently define abuse. The confirmation of the reliability and validity of the current approach for adolescents or, alternatively, the formulation of an age-specific substance abuse definition and diagnostic criteria appropriate for adolescents could play a key role in the development and evaluation of prevention and treatment programs.

5.21.2.3 Prevalence

5.21.2.3.1 Substance abuse disorders

The epidemiology of substance abuse disorders in adolescents has rarely been investigated, with the vast majority of research focused on prevalence of substance use more generally. Moreover, comparison across studies has been impeded by factors such as nonuniform definitions of abuse, the particular diagnostic system employed, and the type and age of sample selected. Using the *DSM-III* system, for example, Kashani et al. (1987) found a prevalence of 5.3% for alcohol abuse or dependence disorders and a 3.3% for drug abuse or dependence disorders in a community sample of 15-year-olds. Deykin, Levy, and Wells (1986), using the same system, found a prevalence rate of 8.2% for alcohol disorders and 9.4% for drug disorders in a young college population ranging from 16 to 19 years of age. Also focusing on older youth, aged 17–19 years, but using the *DSM-IIIR,* Reinherz, Giaconia, Lefkowitz, Pakiz, and Frost (1993) found a prevalence of 34% for alcohol abuse disorders and 9.8% for drug abuse disorders. Although the rates of alcohol disorders seem particularly high in this study, Cohen et al. (1993) examined two age groups, 14- to 16-year olds, and 17- to 20-year olds, with reported rates of 4.1% and 3.1% for younger boys and girls, respectively, and 20.3% and 8.9% for older boys and girls, respectively. The estimates vary widely and more uniformity in methodology is needed for developing a foundation of empirical work before any conclusions about epidemiology of substance abuse disorders in adolescents can be drawn.

5.21.2.3.2 Substance use survey data

Compared to substance abuse disorders, prevalence of substance use among adolescents has been much more intensively studied. Data are regularly obtained through two national surveys, the National Household Survey on Drug Abuse, a federal project studying illegal drug use in the USA by adults and adolescents since 1971, and the University of Michigan Monitoring the Future project, which focuses on high school seniors. These surveys have revealed a general pattern of increasing substance use among adolescents through the late 1970s and early 1980s, followed by marked declines through 1991. The senior survey data (Johnston et al., 1993), for example, shows that peak lifetime use of alcohol (i.e., having ever used) among high school seniors was 93.2% in 1980, but use in the past month declined from 72.1% in 1978 to 54.0% in 1991. Binge drinking (i.e., having an episode of five or more drinks on one occasion in the past two weeks) among seniors peaked in 1981 at 41.4%, but had dropped to 29.8% by 1991, and daily drinking peaked in 1979 at 6.9%, but had dropped to 3.6% by 1991. Similarly, lifetime use of marijuana peaked in 1980 at 60.3%, with highest daily use in 1978 at 10.7% and lowest use reported for 1991 at 2.0%. Stimulant and cocaine use peaked later, with peak past year stimulant use at 20.3% in 1982 and cocaine use at 13.1% in 1985. The percentage of past month stimulant use dropped from 10.7 in 1982 to 3.7 in 1990, and cocaine use dropped from 6.7 in 1985 to 1.9 in 1990. Other drugs use patterns have shown similar patterns of peak and decline, although it is interesting to note that lifetime prevalence of alcohol use has not shown the same sharp declines as for other drugs.

Recent survey data suggest that drug use may be on the rise again. According to the National Household Survey (Substance Abuse and Mental Health Services Administration [SAMHSA], 1996), the rate of past month illicit drug use among adolescents aged 12–17 years increased from 8.2% to 10.9% between 1994 and 1995, a rate which has doubled since 1992. Past month use of alcohol in 12- to 17-year-olds had fallen from 25.2% in 1988 to 15.7% in 1992, and was up to 21.6% and 21.1% in 1994 and 1995, respectively. Significant increases were also reported for past month marijuana use, from 6% in 1994 to 8.2% in 1995, continuing an upward trend since 1992. Similarly, between 1994 and 1995, cocaine use increased from 0.3% to 0.8% and hallucinogen use increased from 1.1% to 1.7%.

Tobacco use appears to be on the rise as well. The Youth Risk Behavior Survey reported current cigarette use among students in grades 9–12 increasing from 27.5% in 1991 to 34.8% in 1995 (Centers for Disease Control and Prevention, 1996). These findings are consistent with the Monitoring the Future project, which reported rates of smoking by 10th and 12th graders increasing, respectively, from 20.8% and 28.3% in 1991 to 27.9% and 33.5% in 1995. These rates are alarming when considering that roughly 11% of students reportedly smoke a half-pack per day or more (Johnston et al., 1993) and this percentage may be rising as well.

The rate of first use of marijuana, cocaine and crack, inhalants, and other substances, including adolescent alcohol use, has also risen sharply in the same period. First use has shown utility in predicting prevalence rates several years later. Increases in this index now could indicate continuing rise in prevalence for several years.

5.21.2.3.3 Prevalence by age, gender, race, and ethnicity

In general, prevalence rates for the use of alcohol and other substances increase with age. In 1993, for example, the Monitoring the Future project found that past month drinking to the point of intoxication was 28.9% for 12th graders, 19.8% for 10th graders, and 7.8% for 8th graders. Similarly, use of marijuana was 10.9% among 10th graders, but only 5.1% among eighth graders. Inhalant use is one exception, with past month use reported at 3.3% for 10th graders and 5.4% for eighth graders, based on 1994 data. This exception may result from the decreased availability of drugs in junior high and middle schools, compared to high schools, leaving glue or paint cans more readily available for getting high. Despite lower rates overall, trajectories of use for the younger age groups suggests there is reason for concern. That is, during the same period of time the senior survey revealed declines in cocaine, alcohol, and other drug use among seniors, use of these same substances increased among eighth graders.

Comparisons for gender have consistently shown that males tend to use alcohol and drugs in higher proportions than females, especially at higher levels of use (Johnston et al., 1993). The exceptions are sedatives, stimulants, and smoking tobacco, where rates are similar for males and females (Johnston et al., 1993; SAMHSA, 1996). Also, the fall and rise in prevalence rates over time appear to have been the same for male and female adolescents (SAMHSA, 1996).

According to Bachman et al., (1991), Native American adolescents had the highest prevalence of use for cigarettes, alcohol, and most other drugs; Anglo/European Americans (i.e., non-hispanic whites) had higher rates of use than Hispanic Americans, African-Americans, or Asian-Americans. However, National Household Survey data for 1994–1995 revealed no ethnicity differences in smoking (SAMHSA, 1996). With respect to changes in rates over time, during the period of overall declining use (i.e., through 1992) rates of use among non-hispanic whites showed dramatic declines, whereas rates for black and for Hispanic youth remained relatively steady. Prevalence rates across culture and race should continue to receive careful scrutiny. If these patterns hold, research will be needed to understand the mechanisms by which substance use became entrenched in these groups and to examine the necessity of developing treatment programs individually tailored to the needs of particular groups.

5.21.2.4 Etiology

5.21.2.4.1 Risk and protective factors

Although a broad spectrum of factors has been associated with the initiation and maintenance of substance use, no single etiological theory or model adequately accounts for the marked heterogeneity of patterns of substance abuse disorders. A number of researchers have adopted a risk factor perspective as a way to understand the multiple determinants and antecedents of drug use and abuse, including biological, cultural and societal, interpersonal, and intrapersonal factors (Hawkins, Catalano, & Miller, 1992). Although biological influences such as genetic, physiological, and biochemical factors have been shown to affect susceptibility to drug use, these factors have not accounted for large proportions of the variance. Because substance abuse is a complex phenomenon, any single-factor biological cause or theory is unlikely (Bukstein, 1995). Within the broad cultural and social context, substance use can be influenced by factors such as poverty, the existence of laws and social norms favorable toward substance use, and the general availability of alcohol and drugs. Intrapersonal influences include a wide range of individual cognitive and behavioral factors (e.g., positive attitudes toward drug use), aggression and other disruptive behavior problems, and low commitment to education. General findings on interpersonal factors have included familial influences such as: parent and sibling use, parent attitudes toward use, parenting practices, poor communication and parent–adolescent conflict, and parent–child bonding. In addition, poor peer relationships or having friends who use drugs increase the risk for use.

Researchers have also identified a variety of protective factors across the cultural/social, interpersonal, and intrapersonal domains that influence the likelihood of substance use initiation or reduce level of drug use. These factors may moderate the relationship between risk factors and use/abuse, or may have a direct effect on reducing drug involvement (Newcomb, 1995). Sanctions against drug use, family support, self-acceptance, and religiosity are but a few of the protective factors that have been identified (cf Hawkins et al., 1992).

The factors influencing substance abuse are likely to be interdependent and bidirectional. For example, Dishion, Patterson, and Reid (1988) found that parental drug use had both a direct effect, believed to result from modeling and opportunities for use, and an indirect effect, resulting from impaired parental control when parents were under the influence of drugs or alcohol. Similarly, findings of increased stress, increased conflict, highly charged negative affect, lack of openness, and poor cohesion in families, as well as the tendency of adolescents to seek support in relationships outside the family, may all have reciprocal influence. One model suggests that adolescents may not directly imitate their parents' use of specific drugs, but they may be exposed to observing that drug use is one method of coping with psychological stress (Kandel, Kessler, & Margulies, 1978). Effective problem solving may, in turn, attenuate drug use by providing an alternative for coping with stressful life events and family disturbance. Examining another aspect of influence, Duncan, Duncan, and Hops (1994) found that the largest effects of family cohesion on adolescent substance use occur in middle and later adolescence. Taking their results together with other research (Dishion et al., 1988; Patterson, Reid, & Dishion, 1992), they suggested that family influence may vary in a curvilinear fashion over time, with a low point in early adolescence when peer influences peak. Such research begins to tease apart the complex interactions among risk and protective factors associated with substance abuse and holds promise for much needed model development for adolescent substance abuse.

Although the mechanism by which risk and protective factors exert causal influence is poorly understood, Bry, McKeon, and Pandina (1982) found evidence that substance abuse derives from the sheer number of risk factors rather than the presence of any one factor or particular set of factors. These findings have been corroborated by Newcomb and his associates who also found that exposure to more risk factors was not only correlated with use, but predicted increasing drug use over time, providing support for a multiple etiological pathway model of drug use (McGee & Newcomb, 1992; Newcomb, Maddahian, & Bentler, 1986). The risk and protective factor model is a useful one for predicting youth who may develop substance abuse problems and for identifying specific targets for intervention. A limitation of the risk and protective factor model is that, in the absence of longitudinal research, we cannot distinguish between etiological factors, through which we may discover avenues of control, and factors which are merely antecedents or correlates of abuse and have common causes.

5.21.2.4.2 Theory development

Within the substance abuse literature, conceptual models are abundant (Lettieri, Sayers, & Pearson, 1980). In addition to the risk or vulnerability model, models proposed to explain the development of substance abuse disorders range from biological to spiritual and from intrapersonal to sociocultural. Two quite narrow models are the educational model, which views abuse as resulting from a lack of accurate information, and the disease model, which views abuse as irreversible and requires total abstinence to manage the disease. Although these perspectives may not be incompatible with other models, they fail to account for much of what is currently known about the correlates of abuse.

More comprehensive theories can be organized within the broader framework of intrapersonal, cognitive, learning, conventionality/social attachment, and interactional models (Petraitis, Flay, & Miller, 1995). Intrapersonal perspectives place more emphasis on characteristics of adolescents themselves, including personality traits, affective states, and/or behavioral skills, in the etiology of substance use. Although the self-medication hypothesis has been articulated in cognitive-behavioral frameworks as well, the role of substance use as a coping mechanism is an example of an intrapersonal (psychodynamic) perspective. Low self-esteem and self-derogation are also central intrapersonal constructs in theories of etiology.

Cognitive theories focus on the role of adolescents' perceptions of use in decision making related to the initiation and continuation of substance abuse. Attitudes, normative beliefs, and substance use expectancies, as well as self-efficacy, influence the evaluation of the benefits of use (e.g., peer approval) and the costs of use (e.g., health dangers) in decision making.

Operant learning perspectives view substance use in the context of the antecedents and consequences surrounding the behavior. In the presence of stress, for example, substance use may result in tension reduction, regulation of negative affect, or social enhancement, any of which may serve to reinforce use and thereby increase the likelihood that substance use will recur in the future. The social learning model is expanded to allow for cognitively mediated learning through observation and imitation of models (e.g., parents, siblings, or peers) who use substances and it includes self-efficacy beliefs and coping as key concepts.

The conventionality/social attachment approaches stem from sociological theories of control which argue that strong commitment to society, families, schools, and religions inhibits the expression of deviant impulses that all individuals share. Substance use, then, is but one manifestation of a broader cluster of unconventional or problem behaviors which develops in the context of weak conventional bonds, and are maintained through social learning and contingencies in the environment.

Family models view problems such as substance abuse as maladaptive behaviors expressed by one or more family members, but reflecting dysfunction in the system as a whole. The behavior may be viewed as serving an important function in the family, allowing the family to cope with internal or external stressors or maintain other processes that have become established in the organization of the system.

Integrative theories are increasingly complex, but account for more of the findings in the research literature (Petraitis et al., 1995). For example, family interaction theory (Brook, Brook, Gordon, Whiteman, & Cohen, 1990) incorporates family factors, social learning, and intrapersonal characteristics known to affect substance use. Problem-behavior theory (Jessor & Jessor, 1977) emphasizes unconventionality, but also incorporates cognitive, intrapersonal, social learning concepts and accounts for substance abuse and a variety of other deviant behaviors such as juvenile delinquency, poor school performance, and precocious sexual activity.

Flay and Petraitis have attempted to organize the array of theories focusing on substance use etiology into one comprehensive macromodel (Flay & Petraitis, 1994; Petraitis et al., 1995). Their model of triadic influence assumes that health-related behaviors such as substance use are most immediately controlled by decisions or intentions that are a function of three streams of influence: (i) cultural–environmental factors which influence attitudes, (ii) social situation–contextual factors which influence social learning and normative beliefs, and (iii) intrapersonal factors which influence self-efficacy. These streams have different origins and flow through causal factors which are organized into levels ranging from very proximal to distal to ultimate. The stream of influence, independently and in interaction with one another, are recognized as having both direct and indirect effects on behavior (Flay & Petraitis, 1994). This work highlights the complementarity of existing theories and may provide a useful structure for identifying gaps in our knowledge base with respect to etiology.

5.21.2.5 Developmental Course

One avenue which may hold promise for differentiating nonproblem use from more serious substance involvement is research examining the developmental trajectory associated with initiation and progression of use. Before substance use becomes problematic, adolescents pass through a stage during which they are not committed to continuing use and have not integrated substance use as a regular part of life (Clayton, 1992). Typically, adolescents who become abusers follow a relatively invariant sequence for drug use, beginning with alcohol and/or cigarette use, followed by marijuana, and then other hard drugs. This progression from "soft" to "hard" drug use, the "gateway" phenomenon (Kandel, 1975), has been confirmed in a number of studies (Andrews, Hops, Ary, Lichtenstein, & Tildesley, 1991; Kandel, Yamaguchi, & Chen, 1992; Welte & Barnes, 1985). Moreover, Ellickson, Hays, and Bell (1992) found that weekly alcohol use followed marijuana use and preceded use of all other illicit drugs, and that weekly smoking formed a distinct stage between initial use of pills and other hard drugs.

According to Kandel et al. (1978), different factors may predominate each stage of use or predicting the progression to other stages. Their findings suggested that parent modeling may have greater influence on the use of alcohol and tobacco, whereas peers may have greater influence on marijuana use. The use of other illicit drugs was more related to family relationship disturbance and general psychology dysfunction. Thus, although dysfunctional use of drugs can be generally characterized by increasing quantities and varieties of drugs used, understanding substance abuse disorders may involve not only identifying the types and number of substances adolescents have used and the quantity and frequency of use, but also the sequencing or patterning of use, as well as the factors predominating each stage. As Dishion et al. (1988) noted, different models may be required to explain the variations in patterning and progression of use.

5.21.3 CONCEPTUALIZATION AND CLINICAL FORMULATION

5.21.3.1 Multimodal Assessment

Assessment approaches range from narrow inquiry into substance use behavior to broad, multifaceted approaches which address use patterns, problem consequences, other aspects of use (e.g., drug use expectancies, normative beliefs, or readiness to change), and functioning across multiple domains (e.g., school, family, or leisure time). The purpose of the assessment, or the question the assessment is intended to answer, should determine the type of information obtained, how the information is obtained, and who provides the information. A self-report screening instrument summarizing substance use quantity and frequency may be sufficient to determine need for further evaluation among youth at risk for substance abuse problems. However, more comprehensive approaches are often used in establishing a diagnosis, evaluating treatment needs (i.e., inpatient or detoxification), developing a treatment formulation, or evaluating treatment effectiveness.

The main source of information is usually the adolescent, although collateral information is often obtained from parents or others in the social environment (i.e., teachers, siblings, or peers). Methods for assessing substance abuse include interviewing, questionnaires, checklists, rating scales, and physiological measures (e.g., urine toxicology screens). Observational measures are sometimes used to examine particular aspects of adolescent functioning, such as family and peer interactions (Hops, Tildesley, Lichtenstein, Ary, & Sherman; 1990), and self-monitoring has been used with adults (Sobell & Sobell, 1995).

In general, assessment of adolescents requires some recognition of the cognitive developmental level of the adolescent, attention to issues of engagement in the process and the need for establishing rapport, and careful consideration of issues of confidentiality. Although the validity of self-report of use has been questioned, adult studies have shown that direct self-report measures have high sensitivity in detecting substance use problems, and compare favorably to biomedical measures such as blood and urine tests (Sobell & Sobell, 1995). Similarly, some support has been found for adolescents (Bailey, Flewelling, & Rachal, 1992; Needle, McCubbin, Lorence, & Hochhauser, 1983), but more systematic examination is needed to address this issue in adolescent populations (Winters & Stinchfield, 1995).

5.21.3.1.1 Methods for assessing substance use

Almost all measures of substance use behavior focus on some type of direct self-report of frequency (e.g., how many days per month use occurred) and intensity of use (e.g., number of drinks consumed). The majority of adolescents referred for treatment use multiple substances, necessitating inquiry about the quantity/frequency of use of each specific drug type. Two general approaches to assessing frequency and quantity of substance use have been described: quantity/frequency self-report questionnaires and calendar-based interviewing methods. Many self-report instruments measuring use of alcohol and other substances provide summaries of use behavior or are scaled in a way that precludes detailed assessment of use (e.g., 0 times per week, 1–2 times per week, 3 times or more per week). As a result, such measures fail to capture the patterning of use with any degree of precision that would allow for the calculation of peak blood alcohol concentration, a potentially important indicator of dangerous or even life-threatening alcohol use. Summary measures have also been shown to produce significantly lower estimates of use (Sobell & Sobell, 1995) and may also fail to detect reductions in use among very heavy users who, for example, could decrease their use from daily to three times per week.

An alternative method is the time line follow back procedure (Sobell & Sobell, 1995), a structured interview technique that samples a specific time period, using a monthly calendar and memory anchor points to reconstruct daily consumption during the period of interest. A number of studies have compared the methods, including quantity/frequency measures and time line follow back, finding generally similar estimates. In principle, the time line follow back may offer the most sensitive assessment for adolescents, having the advantage of assessing the widely variable drinking patterns that often characterize teen drinking and that might not be modeled adequately by the averaging approaches (Leccese & Waldron, 1994). In a recent study, initial evidence for the internal reliability and convergent validity of the time line method for adolescent drinkers was found (Waldron, 1996). Moreover, a group of adolescents who were classified as nonproblem drinkers on the basis of the *Adolescent Drinking Index* (Harrell & Wirtz, 1989), a standardized alcohol screening instrument, were identified with substantial amounts of binge drinking. Of 67 nonabstaining youth who scored below the cut-off on the standardized instrument, half were reporting peak blood alcohol concentrations between 0.10 and 0.48 ($M=0.11$), levels which suggest these youth may have been good candidates for harm reduction interventions. These findings support the use of time line follow back with adolescents and point to one direction for future research.

Urine toxicology screens and other biomedical markers can be valuable for corroborating self-report (O'Farrell & Maisto, 1987). When multiple measures, such as self-report, urinalyses, and collateral reports attained by interviewing parents or peers, converge to give the same results, there is greater confidence in the validity of measures. Another useful aspect of biomedical tests is the potential for a "bogus pipeline" effect, creating the impression that there is an accurate check on self-report and thereby increasing honesty in descriptions of one's substance use (Miller, Westerberg, & Waldron, 1995).

5.21.3.1.2 Diagnosis

Several interview instruments have been designed specifically to determine whether an individual meets currently established criteria for disorders of substance abuse and substance dependence according to a specific taxonomic system. The *Adolescent Diagnostic Interview* (Winters & Henly, 1993) is one such system which covers *DSM-III-R* symptoms of psychoactive substance use disorders and thereby assumes the applicability of adult syndromes to adolescents. This structured interview explores the adolescent's drug use history and signs of abuse or dependence for several drug categories, and also covers levels of functioning and psychosocial stressors. Diagnosis, as a binary (present vs. absent) process, represents a gross indicator of problem use with limited utility when used in isolation or as an outcome measure in treatment research. As a treatment issue, however, adolescents whose use is prolonged and heavy without periods of abstinence must be assessed for dependence, since physiological withdrawal may require specific medical or psychological interventions (Kaminer, 1994).

5.21.3.1.3 Screening instruments

Screening instruments are designed to identify the potential presence of a particular problem. As such, they are typically used as a preliminary step in assessment, as a way of determining if further, more comprehensive assessment is necessary. As noted in the discussion of time line follow back, one limitation of screening instruments is their reliance on cut-off scores for decision making. With lower cut-off points, instruments can inappropriately identify adolescents as needing more extensive assessment or intervention, whereas higher cut-off can fail to identify adolescents who are in need of additional services. Moreover, the reduction of a continuously distributed variable to a binary classification probably sacrifices predictive power. Conversely, screening instruments are characteristically easy and inexpensive to administer and are especially useful in settings where large numbers of adolescents must be screened in a short period of time, such as within the juvenile justice system, adolescent medicine units, or general mental health agencies serving adolescents with varied presenting problems. Table 1 presents screening instruments and basic information about each.

5.21.3.1.4 Comprehensive assessment instruments

In addition to assessing substance use behavior, comprehensive assessments also take into account the consequences of substance use, the contexts within which use occurs, the functions which the use serves in the adolescent's life, and the co-occurrence of other problem behaviors. As noted above, many other classes of variables have been found to be related in complex ways to level of substance use, including age, comorbid disorders, peer factors, personality factors, biological and genetic factors, family functioning, and level of social skills. The existence of these relationships suggests that a comprehensive assessment of adolescent substance use could be enriched by information in these areas as well. More comprehensive assessment procedures usually allow for the examination of adolescents' scores along a continuum or along several continua. These instruments are designed to be given after a screening instrument or other process indicates the need for further assessment of alcohol and drug use. Table 2 displays the main characteristics of six comprehensive adolescent assessment instruments.

5.21.3.1.5 Other substance-related questionnaires

To the extent that substance abuse is multiply determined and is associated with diverse problem behaviors presumably generated by common causes, broad, multidimensional assessment is vital. Newcomb and Bentler (1989) maintained that any focus on substance use, in isolation from the associated antecedents, concurrent events, or consequences constituting the more general problem-behavior syndrome of which substance abuse is a part, will be distorted. A number of other instruments have been used to assess various aspects of alcohol and drug use in adolescents. Among them are measures of alcohol, use attitudes toward alcohol, unconventionality of behavior, and expectancies about alcohol and other drugs (cf Leccese & Waldron; 1994; Winters & Stinchfield, 1995). These instruments can be combined with other measures to assess specific concerns the clinician may have in the formulation of the treatment plan or may be used for research purposes.

Table 1 Characteristics of screening instruments.

Instrument	*Administration method*	*Items*	*Time to administer*	*Psychometrics*	*Information provided*
Drug and Alcohol Problem Quick Screen (DAP; Schwartz & Wirtz, 1990)	Self-report	30	10	Limited validity data	Cut-off for substance use risk; indicates the need for further assessment
Drug Use Screening Inventory (DUSI; Tarter & Hegedus, 1991)	Self-report or computer administered	149	20	Adequate content validity	Functioning measured across 10 domains; absolute problem density, overall problem index, and relative problem density scores
Perceived Benefit of Drinking Scale (Petchers & Singer, 1987)	Self-report	5	1	Adequate internal consistency and divergent validity	Scale scores reflect frequency, intoxication, and problems related to substance use
Personal Experience Screening Questionnaire (PESQ; Winters, 1992)	Self-report	40	10	High internal consistency, adequate discriminant and predictive validity	Indicates the need for further assessment
Problem Oriented Screening Instrument (POSIT; Rahdert, 1991)	Self-report	139	30–45	None reported	Functioning measured across 10 domains, "red-flag" items signal the need for further assessment
Teen Health Advisor (Paperny, Aono, Lehman, Hammer, & Riusser, 1990)	Computer administered	32–62	10	None reported	High-risk behavior evaluation and advice or referral information across several domains
Substance Abuse Subtle Screening Inventory-Adolescent (SASSI-A; Miller, 1990)	Self-report	81	20	Limited validity data, no reported reliability data	Face valid alcohol, face valid other drug, obvious attributes, subtle attributes, defensiveness (two scales), and two experimental scales

Table 2 Characteristics of comprehensive assessment instruments.

Instrument	*Administration method*	*Items*	*Time to administer*	*Psychometrics*	*Information provided*
Adolescent Diagnostic Interview (ADI; Winters & Henley, 1993)	Structured or computerized interview	varies	45–60	Adequate interrater, test–retest reliability, and criterion-related validity	*DSM-III-R* substance use disorders, functioning across several domains, psychosocial stressors, and screens for memory and orientation
Adolescent Drug Abuse Diagnosis (ADAD; Friedman & Utada, 1989)	Structured interview	150	45–60	High interrater, test–retest reliability, adequate concurrent, convergent, and discriminant validity	Problem severity ratings and need for treatment across nine domains
Adolescent Problem Severity Index (APSI; Metzger, Kushner, & McLellan, 1991)	Semistructured or computerized interview	varies	45–60	None reported	Composite score (number of risk factors) and severity rating (need for treatment) across seven domains
Adolescent Self Assessment Profile (ASAP; Wanberg, 1991)	Self-report	203	45–60	Adequate internal consistency	Profile of adjustment, functioning, and substance use across multiple domains
Personal Experience Inventory (PEI; Winters & Henley, 1989)	Self-report, computer administered	276	45–60	Adequate internal consistency, test–retest reliability, concurrent, discriminant and predictive validity	Substance use frequency and severity, personal and environmental risk factors, problem screening and faking
Teen Addiction Severity Index (T-ASI; Kaminer, Bukstein, & Tarter, 1991)	Semistructured interview	134	30–45	Adequate interrator reliability	Problem severity and need for treatment across seven domains rated by both client and interviewer

5.21.3.2 Treatment Formulation

How assessment findings should be used in treatment planning has seldom been addressed in the literature. The National Institute on Drug Abuse has developed the Adolescent Assessment/Referral System which advocates an assessment battery approach for identifying potential problems across multiple domains, including substance use, diagnosis, family functioning, and psychological functioning. Using this system, treatment planning determining whether the individual needed substance abuse treatment, family therapy, or other interventions is guided on the problem areas identified in the assessment. The Drug Use Screening Inventory (Tarter, 1990) represents a single, brief screening instrument that provides an assessment across 10 domains of functioning. This instrument was developed as a treatment formulation instrument yielding assessment findings that lead directly to treatment planning. However, evaluations of the effectiveness of assessment systems for treatment formulation and subsequent adolescent treatment outcomes have not been studied.

More often, treatment formulation is guided by the therapeutic orientation of agency or treatment provider. In addition to assessing the topography of substance use and related behaviors for the purpose of evaluating change brought about by intervention, behavioral treatment models might include a functional analysis of the behavior which is incorporated into treatment (e.g., modifying contingencies in the environment on the basis of the functional analysis). Family treatment models may include standardized family assessment instruments and measures of family interaction, but, for treatment formulation, most often conduct assessments of family functioning in an ongoing fashion in the context of family therapy sessions (Alexander, Barton, Waldron, & Mas, 1983).

Some obvious circumstances, such as evaluating the need for medical supervision of detoxification or inpatient treatment for suicidal substance abusers, influence treatment matching for adolescents. Beyond such examples, however, strategies for matching adolescents to treatments on the basis of assessment findings are premature (Project MATCH, 1997). Identifying environmental treatments for medical problems with quite different etiology (e.g., dietary restriction for phenylketonuria) may apply to substance abuse as well, challenging how we think about treatment formulation. And, as Henly and Winters (1989) noted, a variety of paths have been found leading to substance involvement and a variety of paths may also lead out. Given our current level of understanding of substance abuse disorders, treatment formulation should be determined on the basis of what has been shown empirically to work (Wagner & Kassel, 1995).

5.21.4 TREATMENT

5.21.4.1 Psychosocial Treatments

Psychosocial treatment models for substance abuse include the broadest spectrum of approaches in settings ranging from inpatient intervention to street-based harm reduction programs (e.g., needle exchange), from residential living to outpatient primary-care interventions, and from juvenile detention to school- and community-based preventive services provided for secondary and tertiary care. Inpatient programs typically provide a detailed admission assessment, psychosocial evaluation, exploration of chemical use history and assessment of educational, legal, and psychological status (Wheeler & Malmquist, 1987). Program components include group therapy, lectures, work assignments, a therapeutic milieu, attendance at support meetings, family therapy, and recreational activities. Therapeutic communities, used for adolescents with more severe drug abuse, have similar orientations to inpatient treatment but are longer term, with an average length of stay of 6–9 months. Outpatient treatment can include intensive day-treatment programs, services provided by individual, group, and family therapists, and education-based interventions usually offered in larger contexts.

5.21.4.1.1 Traditional and 12-step models

Modalities of treatment offered across the range of settings have included individual, family based, and group therapies based on a wide variety of orientations such as traditional 12-step philosophies, cognitive-behavioral, family, and educational models as well as recreation therapies and vocational counseling. Inpatient and residential treatment programs have traditionally used a milieu approach, a multimodal treatment often including an education component, individual, group, and family therapy, recreational activities. In many clinical settings, approaches to adolescent treatment for substance use problems are based on the philosophy and principles of Alcoholics Anonymous and/or Narcotics Anonymous (AA/NA; Wheeler & Malmquist, 1987). The philosophy holds that individuals cannot effect change on their own. Rather, individuals must recognize a higher spiritual power to attain a healthy (and abstinent) lifestyle, drawing upon resources from within and support from others and following the 12-step process for recovery.

5.21.4.1.2 Cognitive-behavioral models

Behavioral and cognitive-behavioral approaches have been the focus of many preventive intervention programs (Gilchrist & Schinke, 1985; Pentz, 1985) and are increasingly being used to treat adolescent substance abuse (Turner, Liddle, & Dakof 1996; Waldron & Slesnick, 1997). These approaches, based on principles of learning, often incorporate a stress-coping model of substance abuse and focus on teaching adolescents appropriate skills to avoid substance use. Treatment components may include self-monitoring, social skills training (e.g., problem solving or assertiveness), mood regulation (e.g., relaxation training, anger management, or modifying cognitive distortions), and relapse prevention (e.g., drug and alcohol refusal skills). Modeling, behavior rehearsal, feedback, and homework assignments are characteristic of treatment techniques.

5.21.4.1.3 Family therapy models

Family therapy has been a widely accepted treatment for substance abuse, frequently implemented with adolescent abusers (Stanton & Shadish, 1997; Waldron, 1997). Family systems models view substance abuse as a reflection of relationship dysfunction, and treatment is aimed at restructuring the interactional patterns associated with the abuse, theoretically making the abuse unnecessary in the maintenance of system functioning (Stanton & Todd, 1982). Techniques focus on developing the therapeutic relationship, helping family members understand the interrelatedness of their behaviors and the symptomatic behavior in a way consistent with family change (e.g., reframing), and restructuring or shifting family interaction patterns and establishing new behaviors.

Behavioral family models emphasize training parents in contingency management aimed to increase prosocial behaviors incompatible with substance use and decrease substance use behavior. Communication and conflict-resolution skills training are commonly used to enhance families' behavioral repertoires and allow them to resolve problems independently. The increased positive interactions they experience when putting such skills to use are presumed to reinforce the likelihood that the new behaviors will become established patterns.

5.21.4.2 Pharmacological Treatments

5.21.4.2.1 Pharmacotherapy for substance abuse

Mechanisms for pharmacological treatments of substance abuse include treatments which make drug use aversive, provide an alternative substitute for the drug, block the reinforcing effects of the drug, or relieve drug craving or withdrawal (Kaminer, 1994). However, these approaches are rarely used with adolescents because of the particular topography of substance use among adolescents and the potential problems associated with improper use of pharmacological treatments, as well as a host of other practical and ethical considerations. For example, disulfiram (Antabuse) causes intense nausea and other adverse effects when combined with alcohol and is typically used with regular, heavy drinkers who are motivated to achieve abstinence. Noncompliance (i.e., drinking while taking disulfiram) can be medically dangerous. Because adolescents tend to drink more impulsively, consuming alcohol in episodic binges, the potential for noncompliance and subsequent medical complications is high. Thus, apart from the general ethical considerations concerning aversion therapies with adolescents and issues related to consent for treatment, disulfiram would be inappropriate for use with adolescents.

Nevertheless, no pharmacological evidence suggests that adolescents should be treated differently than adults. No specific contra-indications exist for nicotine gum or patch, heroin substitutes such as l-acetyl-methadol and buprenorphine, methylphenidate or other stimulants for cocaine abuse with adolescents (Kaminer, 1994). Substitution of methadone for heroin use may also be helpful in eliminating craving or blocking the euphoric effects of the drug in heroin-addicted adolescents for whom detoxification is contra-indicated (e.g., pregnant teens who abuse heroin). Although access to methadone programs for adolescents is more difficult than for adults, methadone may also reduce harm among adolescent heroin users by eliminating the danger of contracting AIDS from contaminated needles (Kaminer, 1994).

5.21.4.2.2 Pharmacotherapy for dual diagnosis

The most common pharmacotherapy for adolescent substance abusers is the use of psychoactive medications to treat symptoms or disorders coexisting with the abuse. For example, adolescents with a dual diagnosis of substance abuse disorder and major depressive disorder may be treated with antidepressants such as imipramine, amitriptyline, or other tricyclics, or with sertraline or other serotonin reuptake inhibitors. Obviously, in the presence of suicide risk, the cardiotoxicity of any medications less cardiotoxic must be considered. By the same token, use of medications with addictive properties such as benzodiazepines, which may be used for adolescents diagnosed with anxiety disorders, would not be appropriate for adolescents with comorbid substance abuse disorder.

In general, Bukstein (1995) has advised against the use of pharmacological agents for substance-abusing adolescents without significant coexisting psychopathology. The main issue with pharmacotherapy for adolescent substance use problems is lack of any empirical attention. In a rare study, Kaminer (1992) reported on the facilitation of cocaine abstinence in adolescent using tricyclic antidepressant desipramine, with six-month follow-up findings confirming continued abstinence. Future research is needed to validate pharmacological treatments.

5.21.4.3 Efficacy and Effectiveness of Psychosocial Treatments

Compared to the number and variety of treatment approaches implemented in clinical settings for adolescent substance abuse, remarkably little research has examined treatment effectiveness. Prior to 1980, most of the evidence was based on findings from several large-scale studies examining treatment outcomes across different modalities. Rush (1979), for example, found a number of patient characteristics (i.e., older onset, being in school or having a job, absence of other behavioral disturbance, monodrug use) were associated with better outcomes for 2938 adolescents in primarily in outpatient settings, but that treatment variables such as length of treatment were not. The Drug Abuse Reporting Program (Sells & Simpson, 1979), another large-scale study, compared outcomes for 5405 adolescents in four treatment settings: methadone maintenance, therapeutic community, outpatient, and detoxification. Reductions in substance use were found during treatment, although at follow-up only decreases in opiate use were observed. Another large scale study, the Treatment Outcome Prospective Study (Hubbard, Cavanaugh, Craddock, & Rachal, 1985), evaluated treatment outcomes for 240 adolescents participating in residential or outpatient programs. Although reduced substance use was found for both settings, residential treatment clients fared better than outpatient clients. Unfortunately, no control or comparison groups were included in these studies.

5.21.4.3.1 Traditional interventions

One study (Amini, Zilberg, Burke, & Salasnek, 1982), has compared a psychodynamically oriented inpatient drug treatment with an outpatient probation service intervention in a sample of 74 substance abusing adolescents. Subjects were randomly assigned to treatment condition and both groups showed significant decreases in drug use. No between-group differences were found. A number of other studies, however, have examined treatments based on AA/NA philosophy. Friedman, Schwartz, & Utada (1989) evaluated the outcome of a day treatment intervention program using a pre/post design. The program used a modified version of the AA 12 steps, daily meetings, guided group interaction and group therapy, ration-emotive and reality therapy approaches. The mean number of months for follow-up evaluation was 14.6. Of 222 participants, with a mean age of 16.6 years, 85% reported less drug use than when they started in the program. Another pre/post only study was conducted by Alford, Koehler, & Leonard (1991), who examined the effectiveness of AA/NA programs. They evaluated outcomes for 157 substance abusing adolescents treated in an inpatient setting and found that 71% of male treatment completers and 79% of female completers were abstinent six months following discharge. After two years, abstinence among males had dropped to 40%, among females to 61%. Grenier (1985) compared outcome of a residential treatment program based on AA principles with a waiting list control group. The treatment group showed significantly greater abstinence (65.5% vs. 14.3%) two years after treatment.

Multimodal programs have also been examined. Feldman (1983) found significant reductions in substance use for 71 black and Latino adolescents who participated in an intervention consisting of recreational activities, counseling, family intervention, and legal services. Barrett, Simpson, and Lehman (1988) evaluated four community-based drug abuse intervention programs providing individual, group, and family therapy, recreational and community service activities, and substance abuse education. Three months after intake, significant improvements for all problem behaviors were revealed, but no differences were found between programs. Braukmann et al. (1985) compared delinquent adolescents in Teaching Family group homes with living in a treatment-as-usual group home and an untreated group. The Teaching Family group homes, applying skills training, self-government, motivation, relationship development and youth advocacy, showed significant during-treatment decreases in substance use. However, these decreases did not persist at 12-month follow-up.

5.21.4.3.2 Behavioral outpatient interventions

Davidge and Forman (1988) reviewed eight case studies published between 1967 and 1985 which provided limited support for behavior therapy with adolescent substance abusers. These studies were limited by small sample sizes, lack of control or comparison conditions and, in many cases, only anecdotal reporting of substance use behavior. Two of the cases, however, used urine analysis to validate self-report of substance use, lending more strength to study claims. These cases used contingency contracting with the adolescent and parents, focusing on school, work, and relationships (Cook & Petersen, 1985; Fredericksen, Jenkins, & Carr, 1976). The adolescents in both cases had drastically reduced substance use or remained abstinent at post-treatment and at follow-up through one year in one case and three years in the other.

In other behavioral investigations, Duehn (1978) evaluated the effectiveness of aversive conditioning for adolescents with severe drug-use histories. At 6- and 18-month follow-up, completed abstinence was reported for six of the seven youth who had participated in the 14 week covert sensitization training program. DeJong and Henrich (1980) conducted a two year follow-up study of 89 young addicts in a behavior modification program who attended a rehabilitation center for at least seven days. They reported that one-third of the total sample remained drug free. In a set of two studies using a pre/post design, Iverson and colleagues (Iverson, Jurs, Johnson, & Rohen, 1978; Iverson & Roberts, 1980) conducted a community education-based program for parents and adolescents and found significant reductions in drug use at post-treatment and six-month follow-up.

Using a between-groups design, Smith (1983) compared an eight-session school-based group treatment, focusing on skills training in the areas of problem solving, social skills, and self-monitoring, with a no treatment control condition for adolescent marijuana users. Self-reported use was reduced and academic and peer functioning was enhanced for the youth in the treatment. In a residential treatment setting, Hawkins, Catalano, and Miller (1992) found improved role play performance involving avoidance of drug use and interpersonal problem solving in an applied behavioral social skills training intervention in adolescents in a residential treatment center.

For both traditional and behavioral interventions, wide variation with respect to control groups, random assignment, outcome measures, and number and latency of follow-up assessments can be seen. However, none of the studies comparing across two or more intervention conditions found evidence that any treatment approach examined was better than any other. In their review of nonfamily-based treatments, Catalano, Hawkins, Wells, Miller, & Brewer (1990–91) addressed the limitations of these studies and could only conclude that some treatment is better than no treatment. In the absence of more randomized clinical trials including appropriate alternative comparison conditions, no more definitive conclusions can be made. Several federally funded controlled trials of promising treatment approaches are currently underway and are likely to improve the knowledge base with respect to empirically validated treatments for adolescent substance abuse.

5.21.4.3.3 Family-based interventions

In the last decade or so, considerable advances have been made in evaluating the effectiveness of family treatments for adolescent substance abuse, with a dozen or more controlled trials completed or underway (Stanton & Shadish, 1997; Waldron, 1997). Much of the impetus for these advances stemmed from the early controlled studies of family therapy conducted by Szapocznik and his colleagues. Scopetta, King, Szapocznik, and Tillman (1979) investigated whether family interventions need to be ecologically focused, involving multiple systems, or whether intervention within the conjoint family context is sufficient. Although both groups showed improved outcomes following treatment, no differences were found between the two interventions. In another set of studies, Szapocznik, Kurtines, Foote, Perez-Vidal, and Hervis (1983, 1986) compared two variations of structural family systems therapy, conjoint family therapy and one-person family therapy, examining whether family therapy outcome varies on the basis of who participates in the sessions. Families in both intervention conditions showed significant improvement at the end of therapy. Moreover, compared to conjoint therapy, one-person family therapy led to slightly greater improvement for some outcome measures. These studies were limited by small sample sizes, high attrition, inadequate substance use measurement, and the absence of a nonfamily comparison condition. However, like other early outcome studies, the findings of pre/post changes were promising.

Other randomized trials comparing systems family therapy to alternative family-based interventions have also been conducted. Friedman (1989) found pre/post differences comparing the effectiveness of Functional Family Therapy (Alexander & Parsons, 1982) to a parenting skills group intervention. Although no between-group differences were found, 93% of the families in family therapy engaged in treatment compared to only 67% of the parenting group families. In a reanalysis of these data which included treatment dropouts as failures, Stanton and Shadish (1997) reported that a significant difference between the two groups emerged, highlighting the importance of considering differential attrition in conducting treatment outcome research. Lewis, Piercy, Sprenkle, and Trepper (1990) also evaluated an integrative family therapy model, comparing Purdue Brief Family Therapy, to a didactic, family-oriented parenting skills intervention. Both interventions were found to significantly reduce drug use at post-treatment. However, a greater percentage of youth receiving family therapy decreased their use, compared to the parenting group intervention. No follow-up data were reported.

A number of randomized trials have included nonfamily comparison interventions in their designs. Joanning, Thomas, Quinn, and Mullen (1992) compared a family systems intervention to two comparison conditions, a family drug education intervention and adolescent group therapy. The results at post-treatment revealed that family therapy was most effective in decreasing problem behaviors and drug use, with 54% of youth in family therapy abstinent, compared to 29% in the family education condition and 17% in the group therapy condition. Using a more complex ecological intervention, Henggeler et al. (1991) conducted two studies, comparing multisystemic family therapy to individual therapy in the first study and to a treatment-as-usual juvenile probation supervision intervention in the second. As had been found in treating delinquents, multisystemic family therapy produced significantly better outcomes at post-test. Liddle et al. (1993) compared a multisystemic, multidimensional family therapy to two alternative treatments: adolescent group therapy and a family education group. All three conditions were associated with reduced substance use, with greatest and most consistent improvement in the family therapy condition, in which youth decreased their use from daily to about once a week for alcohol and marijuana, with 30% abstinent. Group therapy also showed gradual decline in drug use from pretreatment to follow-up, not apparent at post-treatment, and the authors suggested that the effect may have resulted from the delay between adolescents putting newly acquired skills into use and deriving benefit from implementing them.

Two behavioral family therapy trials have also been conducted. Azrin, Donohue, Besalel, Kogan, and Acierno (1994) compared behavioral family therapy to a process-oriented, nondirective (supportive) adolescent group therapy intervention. Compared to the supportive group intervention, behavioral family therapy produced greater reductions in substance use and improvements in other areas of functioning. In another behavioral family therapy evaluation, Krinsley and Bry (1997) examined the impact of a school-based behavioral family therapy intervention compared to a school-based intervention only condition. Relative to pretreatment, students who participated in family therapy showed greater reductions than students in the school intervention alone during the 15 months following treatment. The differences between groups appeared even greater over time, illustrating the importance of conducting follow-up assessments.

In the first controlled study of its kind, Turner, Liddle, and Dakof (1996) recently reported results of a randomized clinical trial comparing cognitive-behavior therapy and multisystemic family therapy for adolescent substance abuse to a treatment-as-usual condition. The cognitive-behavioral and family interventions both included individual and conjoint family sessions. The cognitive-behavioral condition included self-monitoring, communication and problem-solving skills training, contingency contracting, and substance refusal skills, while the family condition was a multidimensional family intervention (Liddle et al., 1993). Preliminary results indicated that both of the experimental treatments produce greater reductions in substance use relative to treatment-as-usual. However, some findings suggest that although there were no differences between the two active conditions through six month follow-up, the cognitive-behavioral treatment appeared more effective through a 12 month follow-up. However, data analysis is incomplete and no conclusions can be drawn until the final results are examined.

Taken together, the results of controlled clinical trials evaluating family-based interventions suggest that family therapy is an effective treatment for adolescents substance abuse. Only one study (Henggeler et al., 1991) reported finding no differences between family therapy and a nonfamily intervention. Every study demonstrated significant reductions in substance use from pre- to post-treatment. In seven of eight studies comparing family therapy to a nonfamily-based intervention, youth receiving family therapy showed greater reductions in substance use than those receiving adolescent group therapy (Azrin et al., 1994; Joanning et al., 1992; Liddle et al., 1993), family education (Joanning et al., 1992; Liddle et al., 1993), and individual therapy, individual tracking through schools, or juvenile justice systems (Henggeler et al., 1991; Krinsley & Bry, 1997). When compared to parenting skills training programs, family therapy fared better in the Lewis et al. (1990) study and in the Friedman (1989) study when dropouts were included in analysis. Stanton and Shadish (1997) give effect sizes in the their meta-analysis of family therapy outcome studies.

5.21.4.3.4 Treatment engagement and retention

Treatment retention in alcohol and drug abuse populations is a widely recognized problem. Adolescents are at even greater risk for dropping out of treatment, compared with adults, because they are less motivated to change, do not perceive treatment as suitable for themselves, and are more likely to be in treatment because of external pressures (Jainchill, Bhattacharya, & Yagelka, 1995). Kaminer and Frances (1991) prospectively compared treatment noncompleters with completers between the ages of 13 and 18, in an inpatient dual disorder substance abuse treatment program designed specifically for adolescents, hypothesizing that treatments which simultaneously address psychiatric issues would improve treatment outcome. Fifty adolescents completed treatment, 14 did not. Involuntary admission, past treatment, and parental psychopathology had no impact on dropout. A trend towards a higher prevalence of mood disorder and adjustment disorder was found in treatment completers. In contrast, the treatment dropout group had a higher prevalence of conduct disorder. Jainchill et al. (1995) also examined factors related to treatment retention in two residential treatment centers, comparing clients age 17 and under with clients 18 to 20 years old. They found that older clients felt more motivated and ready for treatment and perceived treatment to be more suitable for them. The most consistent predictor of treatment retention was age.

A recent research project evaluating the effectiveness of residential treatment for adolescent substance abuse has received funding through the National Institute on Drug Abuse (Jainchill et al., 1995). Data collection has been completed for 938 adolescents, but follow-up data are not yet available. However, several variables correlated significantly with retention. Consistent with Kaminer and Francis (1991), antisocial lifestyle and poorer psychological functioning may predict early dropout. Other predictors, consistent with Jainchill et al. (1995), included measures of self-esteem, motivation and readiness for change, environmental risk factors, and the interviewer's impressions of the client's likelihood of staying in the program.

Recognizing the problem of engaging drug abusers and their families in treatment, Szapocznik and his colleagues turned their research efforts toward evaluating ways to enhance patient retention in family therapy. In one study, Szapocznik et al. (1988) compared their family systems therapy in combination with an intensive engagement intervention to family systems therapy alone (with engagement as usual). The results were quite pronounced: 93% of the substance abusers and their families in the intensive engagement condition completed intake compared to 47% of the engagement as usual group. Once engaged in treatment, there were no further attrition differences between the groups.

In the second study, Santisteban et al. (1996) replicated the findings of the first study, and even with stricter criteria for treatment engagement they found 81% of the substance abusers and their families in the intensive engagement condition completing intake compared to 60% in the comparison conditions. Moreover, they found that ethnicity was associated with a differential engagement rate in the intensive condition: 97% of the non-Cuban Hispanics in the intensive condition were engaged vs. 64% of the Cuban Hispanics, allowing them to explore further the role of ethnicity in family therapy process. Taken together, motivational issues and their role in retention and recovery should continue as a focus study.

5.21.5 FUTURE DIRECTIONS FOR RESEARCH AND PRACTICE

Research on adolescent substance abuse has been characterized by disparate definitions of abuse, wide variations in subject sampling strategies, and little systematic attention to heterogeneity among adolescents with substance abuse disorders. Such methodological problems may represent primary sources for inconsistency of findings and noncomparability across studies. However, important advances in assessing adolescent substance use have been made in recent years, with the development of a variety of instruments specifically designed for adolescents (Winters & Stinchfield, 1995). Establishing the psychometric properties of these instruments and developing more uniform assessment procedures for research and practice is needed to facilitate the development of treatment formulation procedures and facilitate treatment effectiveness comparisons. Greater collaboration among researchers in this field would also improve comparisons across studies and could yield greater convergence and consistency of findings.

Research is also needed to evaluate assessment strategies more sensitive to patterning of use over time. Some research has shown, for example, that family factors relate more powerfully to stage of substance use than to frequency of use (Brook, Whiteman, & Gordon, 1982). Also, using latent growth modeling to detect similarities and differences in developmental trajectories for substance use, Duncan et al. (1994) found that family cohesion may be more central in delaying escalation of cigarette use than escalation of other substances. With a more detailed and precise assessment of quantity, frequency, and patterning of use, researchers may be able to evaluate the effectiveness and efficacy of family therapies in more sensitive or meaningful ways. For example, forestalling adolescents' progression through the drug use sequence or initiating their return back through the gateway may reflect treatment effectiveness better than overall amount or frequency of use.

Liddle et al. (1993) have attempted to develop a developmentally sensitive treatment model for families of adolescent substance abusers. With respect to gender, different models may also be needed, with girls' substance abuse perhaps best understood in the context of factors such as reasons for using, negative and positive consequences, and expectancies related to use, or family relationships. Considerably more attention has been given to examining the influence of ethnicity on therapy process and outcome (Santisteban et al., 1996; Szapocznik et al., 1988). However, broad-based culturally sensitive treatment models have yet to be developed. Future research should focus on examining the components of treatment models, evaluating the importance of the adolescent development, gender, and ethnicity in relation to treatment effectiveness.

Treatment effectiveness studies have lagged far behind other areas of adolescent substance abuse. Moreover, the vast majority of studies conducted have been plagued with methodological problems. In addition to design and substance use assessment issues, at least half of the studies did not include follow-up assessment, a critical limitation given that several studies conducting follow-up assessments found that patterns of substance use reductions changed over time (Krinsley & Bry, 1997; Liddle et al., 1993; Szapocznik et al., 1983, 1986) and different conclusions could be drawn about treatment effectiveness on the basis of point in time of measurement. Moreover, differential attrition across conditions may have created confounds in interpreting the results of the outcome studies (Snow, Tebes, & Arthur, 1992; Stanton & Shadish, 1997). Some research has also revealed differential dropout rates in substance abusers with dual diagnoses. Thus, comorbid conditions may play a role in the course of treatment as well. More effort needs to be exerted to follow treatment dropouts and examine patterns of outcome related to client heterogeneity.

None of the studies reviewed reported examining therapy process variables which may have been associated with change. Within the broader psychotherapy literature, therapy process and outcome research has shown great promise in isolating therapist, client, and interactional mediators of outcome. The equivocal findings in the clinical trials for adolescent substance abuse highlight the need for incorporating a process perspective in this area of endeavor as well.

A number of family-based clinical trials compared two or more interventions to one another. However, no clear pattern emerged for the superiority of one treatment model over another. Few studies indicated use of a treatment manual, and fewer still used actual adherence ratings to ensure that the components described were actually being delivered. It is possible that no differences on the basis of theoretical model were found because, despite what techniques and procedures treatment researchers say are being implemented, therapists engaged in essentially the same behaviors across models. Alternatively, therapists may have been true to their models, but the effects of common factors present across all interventions such as therapist empathy or warmth and/or treatment expectancies or motivation may have been critical mediators of change.

Creating a motivational context for change represents a major phase of treatment presumed to produce higher engagement and retention rates in some models of family therapy (Alexander & Parsons, 1982). Similarly, Miller and Rollnick (1991) have developed a motivational enhancement approach that has been shown to be effective as an add-on to traditional treatments and as a stand-alone brief intervention for adult problem drinkers. The central feature of this intervention, like the motivational phase of family therapy, is the nonblaming, nonjudgmental stance taken by the therapist. This focus is wholly consistent with the observation of Stanton and Shadish that a nonconfrontational, nonblaming perspective appears to be essential in the treatment of families with substance abusing members and this component of therapy process merits close examination in future treatment studies with adolescents.

5.21.6 SUMMARY

The lack of uniform definition of substance abuse in adolescents has impeded all areas of research including epidemiology, etiology, diagnosis, assessment, treatment development, and treatment outcome evaluation. Studies of risk and protective factors have identified a variety of correlates of abuse that facilitate prediction of who may develop problems or be appropriate candidates for prevention or intervention. The appearance of well-designed clinical trials evaluating interventions in recent years begins to address the issue of optimal treatment strategies for adolescent substance abuse. Research efforts have led to the identification of several treatment approaches that appear to reduce adolescent substance use, relative to no treatment or alternative treatment comparisons. Family therapy, in particular, has engendered substantial empirical support. However, the mechanisms associated with treatment effectiveness have yet to be examined. Researchers need to channel more efforts into prospective model building, incorporating empirical work from the broader substance abuse literature and relying on more uniform, comprehensive, detailed measurement of use. Moreover, psychotherapy process research is needed to examine aspects of the change process associated with better outcomes.

5.22.1 INTRODUCTION

Toilet training is a ritual of considerable interest and concern to parents in all cultures, primitive and advanced (Hindley, Filliozat, Klackenberg, Nicolet-Meister, & Sand, 1965; Whiting & Child, 1964). Over the years, toilet training has been high on the list of concerns of parents with respect to the care of their young children (Ilg & Ames, 1962; Mesibov, Schroeder, & Wesson, 1977; Seim, 1989). It has generally ranked second or third in the list of concerns expressed by parents. The only area to consistently outrank toilet training has been the area of discipline and negative behavior in children.

Perusal of parents magazines and bookshelves with titles of interest to parents indicates a continuing and sustained interest in this area. Most parents spend a significant amount of time and effort in the process of toilet training and regard it as an important accomplishment when the process is complete. In many cultures the process is begun shortly after birth, even though physiological evidence would suggest that children do not have sufficient maturity or control of the muscles and nerves involved to be successful until approximately two years of age.

Although it may be argued that parents are more concerned about this process than they need be, proper toilet training does serve numerous functions. Most obviously, parents wish to have their children toilet trained as early as possible in order to avoid the unpleasant task of changing diapers and sheets. Almost equal in importance, however, is the idea held by many parents that early completion of toilet training indicates that they are good parents and that their child is superior. Beyond this, the importance of proper toileting to good hygiene and prevention of illness should be noted. Finally, many personality theorists point to the importance of toilet training as an early experience in the socialization of the child (Lieberman, 1972). Parents regard the achievement of toilet training as evidence of a major step in their child's progress towards independence and that their child is normal.

For children, toilet training is the first major developmental challenge they face that is more important to others than to them. The child suddenly discovers that his or her ability to control what was once an involuntary internal process is a matter of extreme interest, as well as social significance, to others, and that failures in this area merit the displeasure of parents and peers alike. Freud saw this process as fundamental to the child's development of respect for authority and social mores.

In spite of the importance parents ascribe to toilet training, they may take widely different views about how to accomplish the process. Some parents take the attitude that it is not necessary to directly toilet train children. Their view being that when the time comes, the child will naturally develop (presumably by example of other family members) the idea that he or she should care for eliminative processes and do so on his or her own. Others, however, believe that children will not learn unless they as parents take an active role in the process. As a result, a great deal of time and energy is invested.

One of the most elaborate procedures for toilet training has been outlined in the book *Toilet training in less than a day* by Azrin and Foxx (1976). In this very ingenious approach to toilet training, the child is first helped to toilet train a doll of the type that wets when squeezed. The child and the parent make a game of training the doll. The doll is given fluid after which the parent and child squeeze the doll to produce wetting accidents. If the wetting takes place in an area designated as the toilet, the doll is praised. If the doll wets in the pants, it is scolded mildly. The child helps the doll check the pants and go to the toilet properly. During the time the child is training the doll, the child is given large quantities of favorite beverages to drink in order to produce a full bladder and the need to urinate. Having trained the doll, the parent and child begin a game in which the child does what was demonstrated on the doll. Dry pants' inspections are made every five minutes and a reward of praise or a small treat is given if the pants are dry. Every 15 minutes the child participates in a potty trial in which an effort is made to urinate, whether the child actually has an urge to do so or not. Azrin and Foxx recommend that a child's potty chair be used for these trials since it is easier for the child to mount and sit on such a chair. In addition, they suggest using the type of potty chair that plays a tune when the child urinates. This alerts the parent and child to the fact that urination is occurring and serves as an added incentive to the child. Eventually, on one of the potty trials, the child will be able to urinate. The parent praises the child for this accomplishment and gives the child a small reward. The child is then encouraged to return to the potty chair at any time he or she feels a need to urinate.

At the beginning of the training, the parent assumes a major part of the responsibility by directing the child in the activities prescribed by the training program. The parent begins to fade involvement by reducing direct involvement until the parent is providing only minimal prompts and reminders that the pants should be dry and that the child should go to the potty if necessary. As the child begins to assume responsibility for the process, the potty practice trials are stopped and checks are made for dry pants every 15 minutes. However, if an accident occurs during this time, the parent shows mild verbal displeasure, has the child feel the wet pants, and then instructs the child to carry out a series of "positive practice trials." These trials are carried out by first having the child start from the place in the house where the accident occurred, walk rapidly to the toilet, remove clothing, and sit on the toilet. The child then does this same procedure starting from other points in the house until a total of 10 trials are completed. The child then cleans himself or herself and is given fresh clothing. The parent reminds the child that pants should be kept dry and wetting should be done in the toilet. This procedure continues for several hours (it can generally be accomplished in a long morning or afternoon if the parent and child are not distracted by other family members or other duties) until the child is using the toilet appropriately and independently while maintaining dry pants. Should accidents occur, following the treatment, these are handled by additional positive practice trials.

A couple of other features of this program are also interesting. First, parents are encouraged to give the child a written certificate at the end of the training to mark the accomplishment. Second, a list of friends and relatives, whom the child admires, is developed. During the training, the parent mentions various individuals from this list as individuals who will be happy when the child has learned and who wish the child success. After the child is successful in the training, the child is permitted to call some individuals from the list to report the accomplishment and receive positive feedback. According to Azrin and Foxx, this method is highly successful and most children can be trained in less than four hours. However, it should be pointed out that some studies of this method (Butler, 1976; Matson & Ollendick, 1977) have reported that most parents do better with this training if they have professional consultation in addition to the book.

A much simpler approach to toilet training was developed by the pediatrician Brazelton (1962) who has made numerous other contributions to our knowledge and understanding of the care of children. Brazelton developed this approach over 30 years ago but it is very sound advice and still has much use today. He recommends that the pediatrician begin a discussion of toilet training with the parents at the nine month visit. He notes that it is about this time that grandparents, friends, and relatives begin to put subtle pressure on the parents to see that the child is toilet trained. At this time, Brazelton simply discusses with the parents their attitudes about toilet training, attempts to reduce their anxiety, and encourages them to approach this in a relaxed, unpressured manner. He recommends that toilet training not begin at nine months. At around the age of 18 months, the first attempt is made to train the child.

The training begins by obtaining a small potty chair of the size used by children and identifying this as the child's own chair. An association is also made between this chair and the parents larger toilet chair. The parent then has the child sit on the chair with clothes on so that the chair will not feel cold or unfamiliar at the first sitting. The parent reads to the child and gives the child a small treat such as a cookie while the child sits on the chair. The child is not coerced and is free to leave the chair when they wish. After a week or so of getting the child familiar with sitting on the chair, the child is encouraged to sit on the chair without clothes or diapers. When the child is comfortable doing this, he or she is taken to the chair after a diaper has been soiled. The diaper is changed on the seat and the dirty diaper is dropped in to the pot under the child. The parent points out to the child that this is the eventual function of the chair. After doing this several times over a period of days, all diapers and pants are removed from the child for short periods of time when the parent thinks the child is likely to need to use the toilet. The toilet chair is placed in the room or play area near the child and the child is encouraged to use the potty chair. When the child follows through and uses the chair, the parent expresses approval and encourages the child to do this in the future. At this point, the child can be dressed in loose fitting training pants and taught to remove the training pants in order to use the potty chair when needed.

Nap and night training are not attempted until well after the child has mastered daytime control and shows an interest in staying clean and dry. This may coincide with achievement of daytime control or it may be as much as a year or two later. When the child shows an interest in having a dry bed, the parent can offer to help by waking him or her before the parent goes to bed so that the child can empty the bladder. In some cases, the parent may also have to wake the child a little earlier in the morning for toileting. The potty chair is placed beside the bed (Brazelton suggests painting the pot with luminous paint as an added incentive) and the child is encouraged to use the potty chair at any time during the night if needed. Brazelton stresses that these procedures should be carried out in a positive and supportive manner with the child. Where there are failures or problems, the parent is urged to stop the process and reassure the child that he or she is not bad for the failure. Optimism is expressed about success at some future time. Brazelton reported extremely good success with this method and, as a result, it has been widely used by pediatricians for many years.

The timing of toilet training is particularly important. As Walker (1978) has pointed out, toilet training is accomplished relatively easily when the child is ready to learn that skill. On the other hand, almost no amount of effort will produce the desired result if the child has not matured sufficiently and is not ready. Walker recommends attempting procedures similar to those outlined by Brazelton for a period of a week or two, when the child appears to be ready. If the learning takes place relatively effortlessly and with little power struggle, the process is complete and has been successful. However, if the child does not appear to be learning and if conflict is beginning to develop around the process, it is best to cease the training and to make another attempt after a period of about 3–6 months. This process is attempted every 3–6 months until the child is successful. It is extremely unwise to get into bitter power struggles and excessive conflict with the child over the process of toilet training. The disruption of the parent–child relationship is a much more serious problem than toilet training itself.

Signs of readiness that may be employed to determine when the first attempt at toilet training can be made have been outlined by Azrin and Foxx (1976). They suggest that the child be evaluated for physical readiness (does the child have enough finger and hand coordination to pick up objects easily and does the child walk easily from room to room without assistance) and instructional readiness (can the child point to the nose, eyes, mouth, or hair; can he or she follow directions to sit down on a chair, stand up, walk with you to a particular place, imitate you in a simple task such as playing patty cake, bring you a familiar object, and place one familiar object with another, for example, put the doll in the truck). A child is considered ready for toilet training when able to accomplish both physical readiness tasks and at least eight out of 10 instructional readiness tasks. Most children achieve this at around 20 months of age.

Brazelton suggests use of similar indices of physical maturation sufficient for toilet training and discusses what he calls "psychologic readiness," which is associated with a desire to control the impulses to defecate and urinate. This desire for control is derived from environmental influences including a secure and gratifying relationship with the parents, resulting in a desire to please them, a wish to identify with and imitate parents and other important adult figures, and the wish to develop autonomy and mastery of the primitive impulses to urinate and defecate. Physical and psychological readiness, according to Brazelton, is achieved by most children at around 18–30 months of age.

There is significant variation in readiness among children, due to the fact that children mature at different rates and often show growth spurts. In general, boys mature more slowly than girls. Individual differences as well as sex differences in developmental rates should be taken into account and children should not be hurried or rushed when they are not ready. Some of the claims of parents who assert that they have trained their children from birth or that their children achieved toilet training skill well before the age of two years should be taken with a grain of salt. Reports of early training are more likely situations in which it is the parent who has been trained to anticipate the child's elimination and to place the child on a potty chair. There is also an understandable exaggeration by parents of their child's accomplishments.

All of the above notwithstanding, the average age at which toilet training is completed varies somewhat from one culture to another. In some countries, there is considerable effort expended to toilet train and children appear to accomplish this goal at a somewhat younger age. Other cultures, which take a more relaxed approach, have statistics which indicate that successful toilet training occurs later in life. The same can be said for socioeconomic levels within a culture. Individuals of higher socioeconomic status generally spend a great deal more effort at toilet training their children and report younger ages for achievement than do individuals of lower socioeconomic status. Unfortunately, precise data on the amount of variability are not available. Therefore, although it is possible to influence the age of toilet training to an extent, by aggressive involvement with the child, the process can only be influenced within certain limits and it is questionable whether the stress and conflict involved are worth it. For example, Whiting and Child (1964), in their classic cross-cultural study of the effects of child rearing on personality, noted that of 22 societies compared there was a wide range of attitudes and expectations regarding toilet training. At one extreme are the Tamala of Madagascar where bowel training begins between the ages of two and three months and the child is expected to be continent by the age of six months. The other extreme is represented by the Dena of Africa where toilet training is not even begun until the child is almost five years of age. Most societies studied began toilet training somewhere between the ages 1.5 and 2.5 years. Those favoring early training found it necessary to use frequent and severe punishment. American culture tends to be mid-range in terms of the age at which toilet training is begun and in the severity of the measures used in training. In the early part of this century, relatively severe and early training practices were the mode. Currently, following the suggestions of Brazelton and Spock, more gentle and gradual approaches are endorsed by most parents.

Given the interest and concern of many parents in the toilet training process, it is not surprising that failures in this process result in numerous requests for professional help. Pediatricians, psychologists, and others who provide health care for children are frequently consulted for advice in treating children who are enuretic (unable to control the process of urination) or encopretic (unable to control bowel function). These two topics and certain related disorders will be considered in the remainder of this chapter.

5.22.2 ENURESIS

5.22.2.1 Phenomenonology

Children who experience difficulty with controlling urine have a number of personal and emotional reactions to this difficultly. First, they are often teased and ridiculed by their peers when the peers learn about it either by seeing a daytime accident or hearing about one that occurred at night. The child's parents generally show considerable anxiety about the fact that their child has not learned to control urine and, as a result, there is often a great deal of displeasure and even disgust directed toward the child. This frequently results in parent–child conflict and, in extreme cases, can even result in child abuse. For a child, it is often a mystery that all of a sudden so many people should be so concerned about a process that was virtually ignored previously. Thus, a two- or three-year-old child who is being toilet trained by the parents may wonder why there has been such a change in attitude and rules regarding this behavior. If bedwetting accidents continue into later childhood years, or if a child who has been dry for a while begins to wet again, he or she may be similarly mystified as to what is happening and why there should be so much social disgrace attached to it. Generally, the child feels that this process is uncontrollable and does not understand why people consider it a fault. Biology is on the side of the young child, at least, because the process of urination begins as a reflex in the infant and then must be controlled by the child as he or she develops. Nevertheless, the parental disapproval, peer ridicule, and seeming inability of the child to do anything about the problem results in considerable anxiety and loss of self esteem. George Orwell expressed this very well in his autobiography. He was a student at an English boarding school and records:

> It was looked upon as a disgusting crime which the child committed on purpose and for which the proper cure was a beating. For my part I did not need to be told it was a crime. Night after night I prayed with a fervor never previously attained in my prayers, "please God, do not let me wet my bed! Oh, please God, do not let me wet my bed!", but it made remarkably little difference. Some nights the thing happened, others not. There was no volition about it, no consciousness. You did not properly speaking *do* the deed: you merely woke up in the morning and found that the sheets were wringing wet. (Orwell, 1970 p. 379)

Orwell did eventually receive two severe beatings for this behavior at the hands of the principal of his school. After these beatings, he did not wet the bed again but the emotional scars remained.

In addition to the significant emotional consequences surrounding the problem of enuresis and the misguided attempts to correct it, there are other social consequences. For example, children often cannot participate in overnight parties, camping trips, and similar events due to the fact that they would possibly wet the bed. There are also significant problems when staying in hotels or motels or visiting relatives and friends, should the child wet the bed. As a result, children are often left out of significant activities because of their "problem."

DeGraaf, a chemical engineer, has described his frustrating experiences with enuresis and unsuccessful treatment in a paper entitled "Forty years of being treated for nocturnal enuresis" (1992). Eventually, desmopressin acetate (DDAVP) solved the problem in his case. Studies have demonstrated improvement in social relationships and self esteem following successful treatment of enuresis (Moffatt, 1989; Moffatt, Kato, & Pless, 1987).

5.22.2.2 Diagnostic Features

The 10th edition of the *International Classification of Diseases* (ICD-10) (World Health Organization [WHO], 1992a) contains the category "non-organic enuresis" (F 98.0) which is described as involuntary voiding of urine during the day or night which is abnormal in relation to the individual's mental age and not due to any organic or structural cause. This condition may have been present from birth (primary enuresis) or may develop following a period during which the child previously acquired bladder control (secondary enuresis). There may or may not be widespread emotional or behavioral disorder associated with this condition. The volume on *Clinical Description and Diagnostic Guidelines* discusses the possible relationship between the two and concludes that there is no simple way to decide if emotional problems result from, cause, or simply coexist with enuresis. The clinician is instructed to make a judgement in his or her own opinion for each case as to what constitutes the main problem. This same volume amplifies the age criteria by stating that there is no clear cut off, but generally the diagnosis would not be made unless the child has reached a chronological age of five years and a mental age of four years. The descriptors employed in this definition are rather vague and very general (the volume on research diagnostic criteria, 1993, is more precise and fairly similar to the American Psychiatric Association's *DSM-IV* [1994]). The *DSM-IV Diagnostic and statistical manual of mental disorders* contains the diagnostic category "307.6 Enuresis" (not due to a general medical condition). This diagnosis is defined much more precisely than that in *ICD-10* in that it requires: (i) there be repeated voiding of urine into bed or clothes, either involuntary or intentional; (ii) the behavior must be clinically significant in the sense that it is either of a frequency of at least twice a week for three consecutive months or the presence of the wetting causes significant distress or impairment in social, academic, or other important areas of functioning; (iii) the child is chronologically or developmentally at least five years of age; and (iv) the disorder is not due to a physiological effect from a substance (such as a medication) or from any general organic medical condition. In the *DSM-IV* system the diagnostician is instructed to specify the type which can be nocturnal only, diurnal only, or nocturnal and diurnal (*ICD-10* permits this but does not require it). The essence of both of these diagnoses revolves around the concept that, in the absence of organic disorder, the child is not controlling the process of urination when he or she should be able to do so (approximately five years of age) and is experiencing distress or impairment of functioning as a result of this condition. It is interesting to note that *ICD-10* mentions primary and secondary enuresis, whereas *DSM-IV* currently makes no mention of that distinction; however, *DSM-IV* is explicit about the need to specify whether wetting is day (diurnal) or night (nocturnal) or both. The decision by the writers of *DSM-IV* to specify "clinically significant" as a part of the definition is admirable, but their choice is certainly problematic at times. The requirement that wetting be at least twice a week for at least three consecutive months; or causing distress or impairment in important areas of functioning is a case of comparing apples with oranges. To start with, the frequencies chosen are fairly arbitrary and overly specific, while the term "distress or impairment" is overly vague. Strictly speaking, if the child wet only once (rather than twice) in any given week during the three month period, the child would not qualify as enuretic. On the other hand, if the child wet only once in a similar period but did so under circumstances that were very embarrassing or upsetting, the child could be diagnosed as enuretic.

5.22.2.3 Prevalence

There have been numerous studies of the prevalence of enuresis and the results vary quite widely from one source to another. The major reasons for these discrepencies appear to be differences in the definition of enuresis, differences in populations studied, sampling variations, and methods of data collection. In spite of somewhat conflicting results, there does appear to be some consensus regarding the rate of enuresis.

Physiologically, all children wet during the day and night at birth. By definition, enuresis is not diagnosed until the age of five. Although *DSM-IV* states that the rate for enuresis at age five is 7% for males and 3% for females, the most commonly reported estimate is that approximately 15–20% of five-year-old children are enuretic (Fergusson, Hons, Horwood, & Shannon, 1986; Oppel, Harper, & Rider, 1968). Rates steadily decline until, by the midteens, only approximately 1–2% of males and less than 1% of females would be diagnosable as enuretic. The spontaneous annual remission rate has been estimated at approximately 15% (deJonge, 1973; Forsythe & Redmond, 1974). In some instances, enuresis continues into adulthood. Studies of military recruits suggest that there is a 1–2% prevalence in young adult males (Plag, 1964). Boys are more likely to have problems with enuresis than girls. Some reports suggest that boys may be twice as likely to be involved as girls; however, these data frequently come from clinic-referred patients, and the higher rate of referral of boys for behavior problems may bias these statistics.

Studies in the community at large show some higher incidence in males but not remarkably higher (Fergusson et al., 1986; McGee, Makinson, Williams, Simpson, & Silva 1984; Oppel et al., 1968). Given that girls mature more rapidly than boys, a slightly higher rate in boys would be expected.

Diurnal enuresis is considerably less prevalent than nocturnal enuresis. For example, Hjalmas (1992a) found that only 3.1% of seven-year-old boys and 2.1% of seven-year-old girls experienced day wetting at least once per week. No doubt due to the fact that it is much less common, considerably less is known about diurnal enuresis. Some have speculated that diurnal enuresis may be more common in females than in males; that it may be more likely to occur in children who show signs of emotional disturbance; and may be more difficult to treat, especially if it occurs in older children (deJonge, 1973; Lovibond & Coote, 1970; Shaffer, 1973). Some clinicians are of the opinion that bedwetting in older teenagers and adults may frequently be related to prior child abuse, especially sexually abuse. Although only a small percentage of night-time wetters also wet during the day, a significant percentage (possibly as much as 50–60%) of those with daytime wetting problems also wet the bed at night (Hallgren, 1956). With respect to the primary vs. secondary distinction regarding enuresis, approximately 85% of all cases are considered primary. There is a tendency, as would be expected, for this to decrease with age. Secondary enuresis generally appears between the years of five and eight (APA, 1994). Enuresis is more prevalent in lower socioeconomic levels and in families where the mother has less education (Bakwin & Bakwin, 1972; MacKeith, Meadow, & Turner, 1973). Although there has not been sufficient research to clarify the reason for this, it is no doubt related to different attitudes regarding hygiene in general and toilet training in particular.

5.22.2.4 Etiology

There are three basic approaches to understanding the etiology of enuresis: biological factors, emotional factors, and learning. Each of these areas is briefly examined to determine what it can contribute to the overall understanding of the etiology of this problem.

5.22.2.4.1 Biological factors

It should be emphasized that urinary incontinence can be caused by numerous organic factors, ranging from anomalies of the nervous system, the bladder, or other structures of the urinary system to various types of bladder infections to secondary effects from chronic disease or other illnesses. However enuresis is by definition a functional disorder and, therefore, not the result of organic factors. Enuresis is functional urinary incontinence. Although specific organic pathology is explicitly ruled out of consideration with respect to the etiology of enuresis, various approaches to understanding the etiology presuppose some sort of general biological or physiological process underlying the problem. A wide range of factors have been proposed in this realm. Two that have a reasonable amount of support from the research literature are genetics and developmental delay. It has long been known that enuresis runs in families and tends to show the same general trends that are characteristic of disorders that are genetically determined (Bakwin, 1961; Elian, 1991; Fergusson et al., 1986).

Although there is fairly general support for the notion of a genetic influence in enuresis, there is very little sophisticated genetic research on this problem and no specific mechanism or gene has been determined to explain the inheritance of enuresis. For example, it is not possible to predict the inheritance of enuresis for specific individuals within a family. The most that can be said is that it runs in families.

Numerous clinicians and researchers over the years have suspected some sort of developmental delay as the basis for enuresis. Developmental delay is a very vague and nonspecific concept. In the present instance, it would no doubt refer to some delay in neurological development. Some studies have indicated that children who are enuretic are slow in achieving certain developmental milestones (MacKeith, 1972) but other studies have failed to replicate such findings. Developmental delays, when noted, are generally mild and it is questionable whether they would be sufficient to account for the presence of a condition such as enuresis, especially since physiologically the ability should be in place by 2–5 years of age.

Closely related to the developmental delay hypothesis has been the idea that a mild form of organic brain pathology may be involved in enuresis. The usual suspect is some sort of epileptic seizure during the night. Although it is true that individuals who have epileptic seizures often lose control of their urine, the majority of enuretic children do not suffer diagnosable seizure disorders and careful research has failed to produce significant pathology in terms of electroencephalograms (EEGs) in enuretic children (Mikkelsen, Brown, Minichiello, Millican, & Rapoport, 1982; Salmon, Taylor, & Lee, 1973).

A great deal of interest has centered recently on the possibility that the antidiuretic hormone (ADH) may be the cause of enuresis for some children. George, Messerli, and Genest (1975) have noted a circadian rhythm variation in the excretion of the ADH vasopressin in normal subjects in which there was an increase in secretion during the night. Other studies indicated that this increase did not occur in enuretic children (e.g., Rittig, Knudsun, Norgaard, Pedersen, & Djurhuus, 1989). Enuretic children with lower levels of ADH have been shown to produce larger quantities of dilute urine than normal children with the consequence that the probability of bed wetting is increased. However, later research has failed to confirm the earlier findings of a relatively direct path from low ADH levels to increased production of urine, polyuria and bedwetting (Evans & Meadow, 1992; Watanabe, Kawauchi, Kitamori, & Azuma, 1994). This approach seems to have some merit; however, considerably more research is needed before it will be fully understood.

Another possible factor of a biological nature in producing enuresis is what has been referred to as low functional bladder capacity. A child with low functional bladder capacity feels the need to urinate with lower amounts of urine present in the bladder than other children, and consequently voids smaller quantities of urine more frequently. Some investigators have reported smaller functional bladder capacity in enuretic children and have speculated that this limited bladder capacity results in night time wetting (Starfield, 1967; Zaleski, Gerrard, & Shokeir, 1973). However, there is evidence that the functional bladder capacities for enuretics and nonenuretics show considerable overlap (Rutter, 1973) and increases in functional bladder capacity have not been shown to be reliably related to improvement in enuretic children (Starfield & Mellits, 1968).

In addition, sleep disorder may be a biological factor involved in some cases of enuresis. Certainly, parents who present their children for treatment of enuresis almost uniformly report that their child is an exceedingly deep sleeper. Unfortunately, studies that have attempted to measure depth of sleep of bed wetters have failed to show consistent results (Mikkelsen et al., 1980). Although it is plausible to assume that some sort of sleep disorder is related to enuresis, no firm conclusion can be drawn until further research is done. Somewhat related to the sleep etiology of enuresis are various reports that have appeared in the literature, suggesting that sleep apnea may be related to the problem. For example, Weider and Hauri (1985), as well as Timms (1989), have reported that use of surgery or mechanical devices designed to improve breathing while asleep have resulted in reduction or cessation of bedwetting in a small number of children where this was a problem. Unfortunately, these reports, to date, are all anecdotal and lacking in scientific control. Even if further research were to substantiate this, it would account for only a small proportion of the total number of cases of enuresis.

Finally, food allergies have occasionally been implicated as a biological factor contributing to enuresis (e.g., Egger, Carter, Soothill, & Wilson, 1992). The idea that diet or food allergies may play some part in production of enuresis is certainly intriguing. Various foods are known to affect numerous other body systems; however, research demonstrating a link between food allergies or diet and enuresis, as well as an explanatory mechanism, is currently lacking. Clearly, more research is needed in this area. Should such factors be determined, they may be useful as a first approach to treatment for some cases and as a supplementary approach in others. Since most individuals overcome enuresis by treatment or spontaneous remission without any significant change in diet, it is almost certainly not primarily due to dietary factors.

5.22.2.4.2 Emotional factors

The idea that emotional factors may play a major role in the development of enuresis has a long history. In fact, in previous years many mental health workers were convinced that enuresis was synonymous with some sort of emotional disorder or neurotic conflict. Enuresis was often thought to be related to depression and that wetting was a type of "weeping through the bladder" (Imhof, 1956) or that it might be associated with some sort of sexual conflict in which the urination was symbolic of ejaculation or lubrication (Fenichel, 1946). Others thought that anger might be the major emotional factor and that the wetting was a type of passive aggressiveness against the mother (Soloman & Patch, 1969). Inappropriate or severe toilet training efforts were often implicated. It was frequently noted that a significant amount of family dysfunction, conflict, and other forms of pathology were present in cases where a child was enuretic. Clinicians and researchers thought they saw certain personality characteristics in enuretic children, most commonly immaturity. However, careful research has failed to support any of these notions. Most of these ideas appear to have resulted from a bias in referral patterns to mental health professionals vs. pediatricians. Most enuretic children are treated by pediatricians. Those who show signs of emotional disturbance are generally referred to mental health professionals. As a result, mental health professionals and their literature developed around the idea that some form of emotional disturbance was involved. Studies comparing large unselected samples of enuretic children vs. nonenuretic children failed to find significant relationships between emotional disturbance and enuresis, or to determine any enuretic personality profile (Cullen, 1966; Tapia, Jekel, & Domke, 1960).

The following points appear to be supported by the bulk of the literature and summarize the relationship between emotional disturbance and enuresis. First, the majority of enuretic children are not emotionally disturbed. Second, most emotionally disturbed children are not enuretic. Third, there is, however, a higher incidence of enuresis among emotionally disturbed children than there is among the general population. This area of overlap is relatively modest but has led to considerable misunderstanding. There is no specific diagnosis, emotional condition, or personality pattern associated with enuresis. Although clinical folklore suggests that secondary enuresis is more likely than primary enuresis to be associated with emotional disturbance, research has failed to confirm this (Fritz & Anders, 1979; Cho, 1984). Although data are minimal and somewhat conflicting, there may be a slight increase in the likelihood that emotional disturbance will be present along with enuresis if the enuretic is female, older, and if daytime wetting is present (Moilanen, Jarvelin, Vikevainen-Tervonen, & Huttunen, 1987; Rutter, Tizard, & Whitmore, 1970: Wagner, Smith, & Norris, 1988). Basically, enuresis and emotional disturbance must be thought of as separate categories, which can overlap. The overlap may be accounted for by the fact that emotional distress inhibits learning the necessary skills to control urine, or the distraction of emotional problems may result in a loss of performance of effective urine control techniques that were previously learned. The conflict and rejection suffered by enuretic children may also create emotional distress. At any rate, in most circumstances, the connection between the two is incidental rather than inherent.

5.22.2.4.3 Learning factors

The third and probably most useful explanation for the etiology of enuresis has to do with learning principles. This approach assumes that enuresis is a learning problem. The basic rationale of the approach is as follows. At birth, the process of urination is essentially reflexive. When a sufficient amount of urine has collected in the bladder, the bladder reflexively empties. Through experience, individuals learn to delay and inhibit this reflex for relatively long periods of time. However, even adults are often acutely aware of the fact that urination is basically reflexive and that they may not be able to inhibit this reflex indefinitely. At these times, finding a toilet facility is essential. During their developmental years, children are attempting to master the basic learning task of controlling this reflexive behavior. Enuretic children may be regarded as children who are experiencing difficulty in learning this behavior.

Children master many different tasks at different rates, and therefore it is not unexpected that some children will be delayed in developing this skill. That boys have more trouble with this than girls fits with the fact that males mature physically more slowly than females. Genetic factors, neurological factors such as developmental delay, and other biological factors may well play a part in predisposing the enuretic child to have difficulty learning this skill. The learning approach can also readily incorporate many features of the theory of an emotional basis for the etiology of enuresis. It is well known that emotionality interferes with learning or disrupts performance based on previous learning. Emotional distress may, thus, result in enuresis or delay the learning of control. In addition, family dysfunction or laxity in toilet training as well as conflict regarding failures in this respect could readily be seen as contributing to poor achievement. Ineffective or inappropriate toilet training methods would also be expected to result in poor learning. Thus, a learning theory explanation of the problem of enuresis fits best with the facts and encompasses all known information effectively. It also leads to effective treatment strategies, as described later in this chapter.

5.22.2.5 Developmental Course

The developmental course of enuresis is relatively easily described. Urinary incontinence is 100% at birth and steadily declines by approximately 15% per year until midteens when it reaches a level of around 1–2% which continues through adulthood. Most children achieve urinary continence between the ages of three and five with girls achieving this task somewhat more easily than boys. Those who do not learn urinary continence by age five or who lose this ability following a period of continence, are labeled enuretic.

5.22.2.6 Conceptualization and Clinical Formulation

5.22.2.6.1 Multimodal assessment

The assessment of enuretic children has been discussed in detail elsewhere (Walker & Shaw, 1988). The first step should always be a physical examination by a competent physician. Since enuresis is defined as a functional problem, the possibility of organic disease or etiology should be ruled out with care. Typically, a pediatrician or family physician would be able to accomplish this by relatively simple and noninvasive procedures involving an examination of the external genitalia, medical history, and urine analysis. Should a medical condition be diagnosed, this should be treated first. Frequently, after the medical condition is resolved, enuresis continues and may require further treatment. The family physician or pediatrician may do more extensive tests or, on rare occasions, refer the patient to a urologist for further testing. Medical tests that are sometimes, but rarely, required involve x ray, urodynamic testing, uroflowmetry, electromyography, cystometrography, urethral pressure profilimetry, and cystoscopy, for example. These tests are described in considerable detail by Maizels, Gandhi, Keating, and Rosenbaum (1993). In the majority of cases where a child is wetting, explanation for the problem will not reside in organic pathology. Nevertheless, when a medically diagnosable and treatable condition is present that should be tended to first.

Once general medical pathology has been ruled out or corrected, an in-depth psychological assessment is in order. This should begin with a careful history taken by interview that will include aspects of a typical intake interview to determine whether or not psychopathology of any sort is present in the child. Should there be suggestions of psychopathology, these should be explored through standard psychological testing and other assessment procedures. In some instances, where there is significant psychopathology, it is clinically advisable to treat the more serious pathology rather than attempting to treat enuresis in the presence of such pathology. The presence of severe pathology interferes with the treatment of enuresis and makes the outcome problematic. It is important to keep this in mind because practitioners who treat enuretic children often receive referrals from physicians that ostensibly are for the purpose of enuresis but, upon examination, reveal severe personal and/or family pathology that is the real reason for referral. Many physicians prefer to avoid confrontation with patients regarding their emotional difficulties and use enuresis as a token for referral.

If severe psychopathology is not present, treatment for enuresis may be undertaken. In cases where there is mild to moderate psychopathology present, a decision will need to be made as to whether the enuresis should be tackled early on or later in treatment. Often, achievement of success in control of urine enhances self-esteem and encourages progress of the child in other treatment. On the other hand, control of urine may not be possible until other problems are dealt with successfully.

Specific to the problem of enuresis, there should be a complete functional analysis including such things as onset of the problem, frequency, amount of urine expelled, number of times the child uses the bathroom during the day, whether or not urgency is present, reaction of the child and others in the family to the problem, discussion of past attempts at treatment (and their success or failure), family history of enuresis, effects on the child's functioning (especially socialization), power struggles that may be going on in the family regarding the problem, motivation of the child and family to overcome the problem, sleeping arrangements and habits of the child and the family, times at which the wetting accidents occur (day or night), whether or not child abuse (physical or sexual) has occurred, and other factors unique to the child that may play a part in the problem. Following this evaluation, the clinician may find it useful to use a scale developed by Morgan and Young (1975) which is designed to evaluate parental reactions to enuresis. In addition to a careful assessment of the motivation to participate in treatment of the problem, the clinician should carefully evaluate the acceptability of the various approaches to treatment that are described later in this chapter. Since there are a wide variety of approaches to the treatment of enuresis, it is wise to involve the parents and child in the selection of the treatment options.

5.22.2.6.2 Treatment formulation

As noted in the section on etiology, there is a wide range of possible factors that appear to have some relationship to enuresis. These factors involve everything from organic illness through biological/physiological predisposing factors through emotional difficulties to learning problems. Formulation of the case when dealing with an enuretic child will involve careful consideration of all possibilities and blending those factors that appear relevant into a treatment conceptualization and strategy. Depending on the particular blend of factors present, different treatment strategies may be expected to have more or less success and may be more or less acceptable to the child and family. As noted earlier, the general framework of a behavioral or learning theory approach has been found most useful by the majority of clinicians and readily incorporates factors from the other two major approaches to etiology. Thus, an overall strategy of viewing the problem as a failure to learn or to achieve competence in performing the task of controlling urine is clinically useful. The clinician can see his or her role as serving as consultant/coach to the child and family as they work on a resolution of the problem.

5.22.2.7 Treatment

Over the centuries, hundreds of different treatments have been attempted for the problem of enuresis. Glicklich (1951) has reviewed the history of the treatment of enuresis in what is now a classic article. From this review, we know that enuresis has been considered a problem since at least 1515 BC, when a medical text of that era recommended juniper berries, cypress, and beer as medication for enuresis. In subsequent times, numerous concoctions were prepared for the treatment of enuresis. Frequently, these concoctions were ground-up organs or tissue from animals such as the flesh of a hedgehog, the claws of a goat, or the trachea of a cock. At other times, they involved ingestion of a wide variety of chemicals, some of which may actually have been dangerous. Likewise, various substances were injected or applied to the sacral area. These applications and injections were theorized to stimulate the nerves in this area, thus producing continence. One of the more barbaric treatments involved burning blisters in the area. It was thought that the blistering would stimulate the sacral nerves. Cauterization of the opening of the urethra with silver nitrate was employed because it was thought that making this portion of the urethra more tender to the passage of urine would force the child to retain the urine. Occasionally, attempts were even made to seal the opening to the urethra with some substance during the night to prevent the passage of urine. Some thought that the warmth from the bed on the sacral nerves might cause bedwetting, or that the position of lying on the back was conducive to wetting. As a result, there were a number of instruments such as spikes or knotted ropes that were wrapped around the child to prevent the child from lying on their back during sleep.

Various other kinds of rotation of the body at different angles (such as elevating the feet, pelvis, or genitals) were also thought to be beneficial in preventing bedwetting. An apparatus popular during the nineteenth century involved insertion into the rectum of a metallic bung shaped like an elongated olive or small hens egg. Soldered to this bung was a piece of metal that simultaneously exerted pressure on the perineum and the coccygeal region of the spine. Whether a child could sleep comfortably with this device in place is open to serious question; however, it did appear to cut down on bedwetting. Various primitive tribes have employed a variety of measures for the treatment of enuresis, most involving punishment or ridicule. For example, one West African tribe pours a mixture of water and ashes on the head of the child. The child is then driven out into the street while other children of the village clap their hands and run after him or her singing "urine everywhere, urine everywhere." The Navajo indians were known to use a treatment during which the child stood naked with his or her legs spread over the burning nest of a Phoebe. This was thought to help because birds don't wet their nest. Mowrer and Mowrer (1938), in their classic article on the development of the pad-and-bell technique for treatment of enuresis, noted that the following treatments had been employed from time to time:

> innumerable drugs and hormones; special diets (including fresh fruit, caviar, and bacilli); restriction of fluids; voluntary exercises in urinary control; injections of physiological saline, sterile water, paraffin, and other inert substances; real and sham operations; passage of a bougie; public application of cantharides plasters; cauterization of the neck of the bladder; spinal punctures; tonsillectomy; circumcision, clitoridotomy, etc.; high-frequency mechanical vibration and electrical stimulation of various parts of the body; massage; bladder and rectal irrigations; Roentgen and other forms of irradiation; chemical neutralization of the urine; sealing or constriction of the urinary orifice; hydrotherapy; local freezing of the external genitalia with ice or chloratyl; elevation of the foot of the patients bed; sleeping on the back; not sleeping on the back; and use of a hard mattress.

Although some of these treatments may be around in one form or another today, most of them are completely without merit and are no longer used. In fact, some are dangerous. The admonition in the hippocratic oath to, "first do no harm," is very applicable to the case of enuresis. One must seriously consider the advantage of eliminating wet clothes or sheets, as opposed to the danger or risk of a treatment contemplated. Whether the danger is the possibility of physical harm to the child or emotional harm and disruption of the parent–child bond, the potential benefits of treatment may not warrant the risk. This is especially true for younger children since time is a definite ally in elimination of enuresis.

5.22.2.7.1 Psychosocial treatments

(i) Support and encouragement

Most books providing advice to parents and most textbooks for clinicians working with children suggest that the initial attempt to deal with enuresis involves talking with the child in an effort to give the child support and encouragement in his or her attempt to overcome the problem. Often, this will involve a brief medical examination so that the child can be reassured that there is nothing physically wrong or dangerous. The parents are advised to avoid conflict or punishment and to praise the child or provide some reward for success. This is often coupled with restriction of fluids, elimination of any drinks containing caffeine (coffee, tea, cola, soft drinks, etc.), and emptying the bladder just before retiring.

(ii) Periodic awaking

A number of different attempts have been made to use waking the child at night as a means of preventing bedwetting (Creer & Davis, 1975; Young, 1964). The simplest form of this intervention is for the parent to wake the child before the parent goes to bed, so that the child can urinate one more time before attempting to sleep till morning. In other versions, parents attempt to determine the time at which the child wets. The child is then woken 30 minutes prior to the anticipated time of the wetting. Over a period of time the waking time is moved in increments closer and closer to the actual bedtime of the child until the last voiding coincides with going to bed. Other versions employ the opposite strategy if the wetting typically occurs just before getting up in the morning. In these cases, the child is woken earlier than normal and prior to the wetting. The waking time is then gradually made later and later until it coincides with the normal time for getting up in the morning. Generally, waking is left up to the parents. However, some clinicians, especially with older children, employ an alarm clock which the child uses to wake up with.

(iii) Retention control and sphincter exercises

As noted earlier in this chapter, many children who have bedwetting problems appear to have a small functional bladder capacity. These children are noted to urinate frequently during the day and to have a great deal of urgency when they need to urinate (Sorotzkin, 1984; Starfield, 1967). The length of time the child is in bed and asleep exceeds the functional capacity of their bladder, resulting in bedwetting.

Consideration of this led to the development of two approaches to treatment that involve exercises (Miller, 1973). The first exercise involves urine retention. The child is instructed to go to the bathroom and to prepare to urinate, but retain urine as long as possible before beginning the urination process. The child is then encouraged to hold the urine longer each time the urge to urinate occurs. Eventually the child develops control to the point where it is measured in minutes. At this time, the child is allowed to leave the bathroom area and return at a later time to void. A delay of between 30 and 45 minutes is generally encouraged between the first urge to urinate and actual voiding. The approach is based on the rationale that urine retention exercises will increase the tolerance of the bladder for larger and larger volumes of urine.

Sphincter control exercises involve having the child start and stop the stream of urine once urination has begun. The sphincter control exercises are based on the rationale that these exercises increase the voluntary control of the sphincter, thus enabling the child to prevent urination.

(iv) Psychotherapy and family therapy

Use of psychotherapy and/or family therapy for the treatment of enuresis is based on the concept that some personality problem or family dysfunction may be the cause of the problem. As indicated earlier in this chapter there is little empirical evidence to support this position. Nevertheless, individual psychotherapy, family therapy, neurolinguistic reprogramming and use of metaphors have appeared in the literature as possible treatments (Crowley & Mills, 1986; Protinsky & Dillard, 1983; Rydzinski & Kaplan, 1985; Selig, 1982; Wood, 1988).

(v) Hypnosis

A variety of case reports and studies have appeared in the literature employing hypnosis in the treatment of enuresis (Banerjee, Srivastav, & Palan, 1993; Collison, 1970; Kohen, Olness, Corwell, & Heimel, 1980). Following hypnotic induction, the child is encouraged to visualize the urinary system and is given suggestions about holding back urine while asleep, or waking to use the toilet if not able to hold the urine back.

(vi) Cognitive interventions

With the increased interest in cognitive approaches to psychotherapy, attempts have been made to develop treatment programs for enuresis based on cognitive interventions. One such approach (Ronen & Wozner, 1995; Ronen, Wozner, & Rahav, 1992) involves four steps: modification of maladaptive concepts, understanding the enuresis process, increasing bladder control, and developing self-control. This appears to be a well designed protocol involving concepts common in a number of approaches to cognitive therapy. In addition, the bladder control phase involves retention control exercises.

(vii) Pad-and-bell treatment

Treatment of enuresis using a urine alarm was discovered by accident in the early part of the twentieth century by a German physician named Pfaunder. Pfaunder was working in a children's institution where the staff were instructed to change diapers promptly for children who were wet, in order to prevent skin irritation and infection. Pfaunder developed a device that was arranged so that when the child wet, a bell rang to signal to the staff that changing of the diaper was needed.

Pfaunder and the staff at the home were surprised to discover that under these conditions the number of wetting episodes decreased and in many cases ceased (Lovibond & Coote, 1970). Later, Mowrer and Mowrer (1938) experimented with variations of this procedure and demonstrated that it was highly effective in eliminating bedwetting in children. Following the work by the Mowrers, numerous devices were marketed that involved placing a pad in the bed of the child that was connected to a bell and/or light.

When the child urinated on to the pad, this completed an electrical circuit resulting in the ringing of a bell and/or turning on of a light to wake the child to go to the toilet.

Thousands of simple units of this sort were sold through the medical aids sections of major department store catalogs. In addition, numerous companies marketed devices through newspaper, magazine, and door-to-door sales efforts. Currently, a variety of simplified devices are available on the market that accomplish the same thing. These simplified devices involve sewing a small electrode into the undergarments of the child which responds when wet and activates a buzzer that is attached via a velcro strip to the shoulder of the child's pajamas or which is worn as a wristwatch. The buzzer wakes the child.

(viii) Multiple intervention package programs

A number of books and protocols have appeared in the literature that incorporate multiple components in the treatment of enuresis. These often involve such components as retention control and sphincter exercises, support and encouragement, pad-and-bell, positive practice, rewards, and periodic waking. Two of the most widely known and more carefully researched programs of this sort are dry-bed training (Azrin, Sneed, & Foxx, 1973) and full-spectrum home training (Houts, Liebert, & Padawer, 1983). An excellent description of the latter is available in *Bedwetting: A guide for parents and children* (Houts & Liebert, 1984). These programs are elaborate and require considerable training and supervision of the parents in order to complete them. Some work best when the treatment is carried out by trained assistants.

5.22.2.7.2 Pharmacological treatments

Although virtually every medication or chemical in existence has been administered to children in attempt to control bedwetting, there are currently only three medications that are used with any frequency (Miller, Atkin, & Moody, 1992). The most commonly prescribed medication is imipramine (Tofranil). The exact mechanism by which this medication is helpful in the treatment of enuresis is not clearly understood. A second medication often used is oxybutynin chloride (Ditropan). This drug reduces spasms of the bladder and appears to make the bladder less sensitive, resulting in an increase in functional bladder capacity. The third medication that has aroused a great deal of interest is desmopressin acetate (DDAVP). This medication is a synthetic form of vasopressin, which is a hormone that stimulates the kidneys to concentrate urine. Concentration of the urine reduces the amount of urine produced during the night, and appears to thereby enable some individuals to sleep through the night without bedwetting.

5.22.2.7.3 Other treatments

A wide variety of other approaches to treatment of enuresis have been employed and advocated at one time or another. For example, acupuncture has been used (Huo, 1988; Tuzuner, Kecik, Ozdemir, & Canakei, 1990; Xu, 1991). Chiropractic physicians have recommended spinal manipulations designed to reduce pressure on various nerves in order to prevent bedwetting (Gemmell & Jacobson, 1989). Dietary restrictions and manipulations have been attempted (Egger et al., 1992). Various surgical procedures, including dental surgery, have also been used (Timms, 1989; Weider & Hauri, 1985).

5.22.2.8 Effectiveness of Treatments

Since there is a spontaneous remission rate of approximately 15% each year and since virtually all people are able to control urination by the teenage years, it is often difficult to know whether a particular treatment has been successful or not. There have been thousands of studies in this area, however, and the following conclusions are justified. First, there is no doubt that the most effective form of treatment is the pad-and-bell (Djurhuus, Norgaard, Hjalmas, & Wille, 1992; Forsythe & Butler, 1989; Scott, Barclay, & Houts, 1992). Application of the pad-and-bell generally results in cessation of bedwetting for between 75% and 90% of cases over an 8–12 week period. Unfortunately, relapse rates are substantial and can be as high as 40% (Doleys, 1977). Reapplication of the procedure upon relapse is generally successful and in less time than the original course of treatment. Occasionally a third or fourth application may be necessary. Two other approaches that have been suggested to deal with the relapse problem are the use of overlearning (Young & Morgan, 1972) and intermittent schedules of reinforcement (Finley, Rainwater, & Johnson, 1982).

The various medications that have been employed have had only modest success. Although medications result in some improvement in most children, they often do not produce total cessation of the wetting and relapse rates are exceedingly high when medications are withdrawn. This, coupled with the ongoing expense and possibly dangerous side effects of the medications, makes these not the treatment of first choice except for short term interventions (Maizels et al., 1993; Thompson & Rey, 1995).

Other than a few anecdotal and case reports, psychotherapy and family therapy have not been shown to have significant effectiveness for enuresis (DeLeon & Mandell, 1966). The initial reports on cognitive psychotherapy indicate that this approach may have a higher success rate than more traditional approaches to psychotherapy (Ronen et al., 1992). Hypnosis has been shown to be effective when properly employed (Olness, 1975). Retention control and sphincter exercises initially showed good results but later research failed to confirm earlier findings (Doleys, Schwartz, & Ciminero, 1981; Harris & Purohit, 1977). Nevertheless, there is still interest in this approach and the sound physiological rationale would suggest that, properly employed, this treatment might be effective. Such approaches as restricting fluids, support and encouragement, awakening schedules, and so forth, are modestly effective with relatively simple cases. However, they are not sufficient for more difficult cases. Numerous reports have made excessive claims for the effectiveness of diet, acupuncture, chiropractic manipulation and so forth. Additional and more sophisticated research is needed on these approaches.

Probably the most effective approaches available are the multiple component programs by Azrin and Foxx, and Houts and his colleagues (Walker, 1995). These have much to recommend them in terms of careful research and demonstrated effectiveness. Their main drawback is the elaborate procedures required by the protocols and the amount of training, supervision, and effort required for successful execution of these programs. Some researchers doubt that the increase in efficiency of these programs over the simple use of a pad-and-bell justifies the amount of effort required.

5.22.2.9 Future Directions for Research and Practice

Walker (1995) has outlined a research agenda for enuresis. Given the amount of interest in this problem and the many centuries of effort to correct it, it is surprising how little is actually known about the process of developing urinary continence. There is currently very excellent and basic research underway in the UK by Fielding, (e.g. Fielding, 1982; Fielding, Berg, & Bell, 1978) and numerous excellent studies in Sweden and Denmark (Djrhuus, Norgaard, & Ritting, 1992; Hansson, 1992; Hellstrom, Hanson, Hansson, Hjalmas, & Jodal, 1990; Hjalmas, 1992b; Norgaard, Hansen, Nielsen, Rittig, & Djurhuus, 1989).

Walker (1995) notes that the various subtypes of enuresis have not been carefully evaluated with respect to etiology and treatment. Thus, we know that there is primary and secondary enuresis, diurnal and nocturnal enuresis, regular and intermittent enuresis, and so forth but we do not clearly understand the differences between these and whether there are treatment implications based on these differences.

Walker also notes that the most effective treatment which has been clearly demonstrated for several decades is some variation of the pad-and-bell. However, this is the least frequently employed treatment. This would appear to be an interesting research area in the sociology of science and medicine.

The third area Walker has outlined has to do with relapse rates for treatment of enuresis. All forms of treatment appear to have significant problems with relapse. More research is needed to develop ways of dealing with this problem.

Fourth, the relationship between bladder capacity and continence should be explored for possible treatment implications. Not all children who wet have small functional bladder capacity and, surprisingly, increases in functional capacity have not been shown to be directly related to improvement following treatment. Why this is so is not understood.

Fifth, the relationship between sleep and sleep patterns is not clearly understood with respect to enuresis. Although it is very expensive and time consuming to do research in this area, more work is indicated.

Sixth, the relative contributions of the components of the various package programs should be carefully evaluated with respect to their necessity. The package programs are successful but extremely elaborate and might be simplified with clarifying research.

Finally, more research is needed on the effects of diet on the etiology and management of enuresis. The same could be said of some of the alternative treatments, such as acupuncture and chiropractic manipulation. In some cases these are not known to be effective or ineffective because data are lacking. In particular, the cognitive and self-control approaches are deserving of more research.

5.22.3 ENCOPRESIS

5.22.3.1 Phenomenonology

The experience of the encopretic child is even more distressing than that of the enuretic child. This is for several reasons. First, the soiling accidents are more messy and more unpleasant in odor than are urination accidents. In addition, soiling accidents occur almost exclusively during the day, whereas wetting accidents are more likely to occur at night in one's own bedroom. As a result, the encopretic child lives in considerable terror that at any time he or she may have an accident that will result in an odoriferous mess as well as a great deal of embarrassment and ostracism by others.

The distress is heightened even more because, as discussed later in this chapter, the child generally is unable to control the encopretic episodes. They occur with very little warning and can not be managed successfully by the child without treatment. The child is frequently ridiculed by peers and referred to as "stinky" or some similar, even more derogatory, nickname. There is considerable conflict between parent and child because parents generally regard failure to control the bowels as a lack of motivation or slovenliness. Sometimes they even think it is an outright affront to the parents competence and authority. The perception, by the child, that all of his or her peers appear to be able to control bowels and that he or she is the only one unable to do so, makes the child feel considerably alienated from humanity and to feel totally incompetent at even basic life processes. This results in a significant lowering of self esteem and a feeling of defeatism. Many of these children feel that if they cannot control a simple thing such as bowel movements, so that they do not offend others around them, how can they control anything, be competent, or achieve in any area. Often, they are mystified as to why they cannot control their bowels and why others become so upset with them when the accidents occur.

In his book, *Worry: How to kick the serenity habit in 98 easy steps*, Robert Morley (1981) humorously notes that his worry in this area began with the requirement in the British school he attended that he and all the other students "write their name in the school register each morning after bowel evacuation."

Beyond these factors, bowel movements tend to be painful for children with encopresis; there is frequently irritation in the anal region from the fecal material; and the day-to-day living of the child may be marked by abdominal pain, gas, and other intestinal discomfort. Occasionally they are frightened by blood in the feces when hard stools scratch the colon and anus. One result of this is that these children often use denial and refuse to acknowledge that there is a problem. A second is that they may become aggressive and hostile toward those around them as a defense for the rejection that they feel from others. Children also frequently resort to subterfuge in hiding their soiled underclothes to avoid conflict with their parents.

James Roosevelt has provided an interesting insight into the problem of encopresis in his autobiographical writing:

> When I first got to Groton I had led so sheltered a life and was so shy that I was afraid to ask where the bathroom was. Hard as it may be to believe, I did what had to be done in my pants or in the bushes. My soiled pants were stuffed in a box, which I buried in the bushes. I suppose I was surrounded by foul smells. Holding back as long as I could, I started to suffer pains. Not knowing the cause, school officials suspected homesickness (well, I was homesick; at home I know where the bathrooms were) and asked my parents to take me home for a few days to ease my adjustment. (1976, pp. 60–61)

5.22.3.2 Diagnostic Features

DSM-IV defines encopresis as the repeated passage of feces into inappropriate places at least once per month for at least three months in a child who is chronologically four years of age (or developmentally the equivalent), in which the behavior is not due to the physiological effects of some substance such as a laxative or a medical illness. The soiling can be involuntary or intentional and the diagnostician has to determine whether or not constipation is present. When constipation is present the condition is referred to as overflow incontinence. The description of encopresis in *DSM-IV* is in very close agreement with the research data and clinical experience of those working in the field. Fecal incontinence is a general term that refers to a lack of control over bowel movements, whatever the cause. Encopresis is a term reserved for cases in which there is no organic basis other than constipation. Indicating that there is no organic basis other than constipation may be splitting hairs a bit; however, constipation is present in the vast majority of encopretic children and contributes to the problem, although it does not signal any serious medical disorder or illness. The constipation is generally behavioral in origin, involving diet and toilet habits. The requirement that the child be four years of age would seem to be unnecessary. Should a child become constipated at any age with resultant encopresis, it would appear to be a significant clinical problem worthy of treatment. This, of course, should be distinguished from the normal soiling or lack of toilet training in very young children (e.g., before the age of two). The *ICD-10* description of nonorganic encopresis describes the condition as repeated voluntary or involuntary passage of feces usually of normal or near normal consistency in places not appropriate for that purpose. *ICD-10* also notes that the condition may be a continuation of normal infantile incontinence beyond the age when bowel control should have developed; it may involve a loss of continence following successful toilet training; or, it may be a deliberate act of defecation in spite of the fact that the child is capable of bowel control. *ICD-10* notes that the symptom may be singular and isolated, or it may be a part of a wider disorder especially an emotional disorder or conduct disorder. The *ICD-10* description notes the possibility that constipation may be present but does not emphasize this as much as *DSM-IV*, and leans rather heavily toward the idea that an emotional disorder may be associated in many cases. Unfortunately, there is little evidence that emotional disturbance plays a major role in encopresis and considerable evidence that the great majority of the cases do involve constipation.

The discussion of encopresis in *ICD-10* also has other problems. For example, describing the feces as usually normal or near normal consistency does not square with the facts. Typically, a large number of the "accidents" consist of stains and rather pasty deposits or streaks on the underwear of these children caused by seepage around the impacted feces in the colon. These accidents are punctuated by large bowel movements of unusual diameter and/or by small, hard stools resembling rocks. Abnormal stools are the result of constipation.

5.22.3.3 Prevalence

As was the case with enuresis, estimates of the prevalence of encopresis vary widely, in large part due to differences in definition employed, populations studied, and methods of gathering data. There are currently no reliable data that indicate the differential rate of various forms of encopresis, such as retentive vs. nonretentive, primary vs. secondary, and so forth. By definition, functional encopresis does not begin before the age of four years. Overall estimates of the occurrence of encopresis range from 1.5–7.5% of children (Doleys et al., 1981). Some of the lower estimates that have been reported in the literature may be due to the fact that many parents are reluctant to discuss or report this problem with respect to their children. Clinicians in pediatric and mental health settings note that parents do not generally volunteer this information and it is obtained only by careful questioning (Walker, 1978). Boys are approximately four to five times more likely to be encopretic than girls (Bellmon, 1966; Rutter et al., 1970). Approximately 30% of encopretics are also found to be enuretic (Levine, 1975).

5.22.3.4 Etiology

Following an extensive review of the literature, Walker (1978) identified three subtypes of encopresis. First, he noted that there are children who can be described as "manipulative soilers." Children of this category soil when it is to their benefit to do so. Thus, some children soil if there is an examination to be given in school that they wish to avoid. The soiling makes it necessary for their parent to come to school and take them home for cleaning. On occasion, soiling appears to be related to anger or desire to distress the parent and represents a form of oppositional behavior. Or, there may be other environmental reasons that determine when the soiling occurs. Both *DSM-IV* and *ICD-10* note that soiling is sometimes intentional.

A second category of soiling is a form of diarrhea or loose bowels caused by excessive stress and expressed through the colon. A possibly related disorder to this is recurrent abdominal pain which may include diarrhea and is thought to be a precursor of irritable bowel syndrome in adults.

The third category is retentive encopresis based on chronic constipation. This is by far the most common etiology of encopresis. It is estimated that 80–90% of the cases fall into this category (Fitzgerald, 1975; Levine, 1975). As with enuresis, there are three general conceptualizations within which the etiology of encopresis may be considered: biological, emotional, and learning.

5.22.3.4.1 Biological factors

As the most common underlying feature of encopresis is constipation, it is quite likely that there are some underlying biological or physiological factors involved. First, some people have a higher constitutional likelihood for developing constipation; this is no doubt genetic (Petti & Davidson, 1991). Likewise, many individuals appear to be genetically predisposed to develop diarrhea under stress. It has also been speculated that some sort of subtle developmental delay may be involved in the development of encopresis (Bellmon, 1996).

5.22.3.4.2 Emotional factors

Early literature on encopresis often assumed a psychodynamic origin for this problem. The symptom was sometimes thought to be a result of an unconscious conflict, anger, depression, or some similar emotional factor. Encopretic children were frequently considered to have a particular personality, possibly involving immaturity, passive aggressiveness, anger, insecurity, anal fixation, anxiety, or low self esteem (Bemporad, Kresch, Asnes, & Wilson, 1978; Hoag, Norriss, Himeno, & Jacobs, 1971). Mothers were often depicted as rigid and masochistic, whereas fathers were thought to be weak, unaffectional, and uninvolved (Bemporad et al., 1978).

Other theories suggested that overly harsh or early attempts at toilet training may be the cause for encopresis (e.g. Hushka, 1942). Although there may be some merit to the idea that emotional factors play a role in the development of encopresis, most studies have failed to indicate such a connection (Fritz & Armbrust, 1982; Levine, 1975). It is probable that if such factors are involved, they are a secondary contributing factor rather than the major factor in most instances.

5.22.3.4.3 Learning factors

The third general rubric under which the development of encopresis can be understood has to do with learning theory. Obviously, manipulative soiling would follow a reinforcement model. If soiling is successful at manipulating the environment and results in reward for the child, the child will use this behavior in the future under appropriate circumstances. Likewise, chronic diarrhea and irritable bowel syndrome may be understood as symptoms of stress and anxiety which have been conditioned to selected stimuli. Finally, as noted, the most common form of encopresis is based on constipation. The development of constipation is based on behavioral factors such as poor dietary choices, failure to establish good toilet habits, withholding of stools, and similar behaviors which result in constipation.

It is likely that any of the three general categories outlined above (biological, emotional, and learning) may be instrumental in the development of encopresis. In many cases they may all be present to some degree or another. In other cases, one or more may be predominant and the main source of the problem. The most general and all encompassing of the three is the learning formulation because it readily incorporates the others and presents a complete description.

5.22.3.5 Developmental Course

The developmental course of encopresis is relatively simple to describe. At birth, fecal continence does not exist. The bowel reflexively empties when sufficient material is present and when the nerve endings in the rectum are stimulated by the presence of a full bowel. As the child develops, it becomes possible for toilet training to occur and most children develop bowel control relatively easily, prior to urinary control. Problems with encopresis tend to develop after control has been obtained and are generally based, as noted, on constipation which develops in the child. With or without treatment, most cases of encopresis cease by the midteen years. Encopresis persisting into adulthood does occur (Rex, Fitzgerald, & Goulet, 1992) but is rare. The reasons for this are not understood. That is, why would encopresis be a common childhood problem but disappear with or without treatment in the late teens? Whether this is related to improved toileting habits or bodily changes in the adult is not fully understood.

5.22.3.6 Conceptualization and Clinical Formulation

5.22.3.6.1 Multimodal assessment

The assessment of the encopretic child must begin with a medical examination. Typically, the physician will obtain a thorough medical history and do a basic physical examination including a rectal examination and palpation of the intestine for presence of fecal mass. The physician will also generally test for blood in the stool and, given the fact that females often have urinary tract infections if they are encopretic, may perform a urine analysis in females. There are a number of more invasive procedures, such as anorectal manometry, fecal studies, rectal biopsies, and barium enemas, which may be needed depending on what the physician obtains in the history and the initial examination. In the vast majority of cases these tests are not necessary. The basic physical examination can be performed by any competent physician familiar with child health. More advanced testing should be done by a pediatric gastroenterologist or other specialist. There are some organic pathologies that occur frequently enough that they must be ruled out before behavioral treatment is attempted. These include Hirschprung's disease (in which a segment of the colon has reduced, or a total absence of, neuralinnervation), congenital hypothyroidism, and pathology of the colon and surrounding structures such as anal stenosis, fissures, and so forth.

Psychological assessment must be broad and multifaceted (Walker & Shaw, 1988). First, there should be a screening assessment of the child's mental and emotional status. If significant psychopathology exists or significant family dysfunction is present, it may be necessary and advisable to deal with these prior to attempting treatment of the encopresis. Encopresis protocols tend to be relatively rigorous and demanding in terms of the amount of effort and the precision with which things must be done. If the child or the family is sufficiently disturbed that they are unlikely to be successful with the protocol, it is not appropriate to add the stress of this approach to the already existing stress. The existing difficulties should be dealt with followed by treatment for the encopresis. Should there be evidence of current psychopathology, standard psychological testing and assessment instruments may be needed to evaluate further the mental and emotional condition of the child or the degree of family disorganization.

The examination should include a thorough clinical interview of the parent and the child to determine the basic characteristics of the soiling in terms of frequency, timing, size of stools, staining of underwear, passage of blood during bowel movements, and other characteristics of toilet habits. In addition, the clinician would be interested in the manner and time at which toilet training progressed and whether or not the child ever achieved control of the bowel. The reaction of the child and the family to the problem and its effect on their interactions, as well as the motivation of each for treatment should be carefully assessed. The clinician should discuss, with the family, previous attempts to deal with the problem and their success or failure. Since diet is often involved in the development of constipation, there should be some exploration of eating habits. The ability and willingness of both the parents and the child to follow a carefully specified protocol are crucial to the success of treatment of encopresis. This should be thoroughly explored and emphasized in the assessment process.

Since the amount of conflict between parent and child regarding soiling is often significant and the family may be dysfunctional, the possibility of child abuse must be considered (Boon, 1991). The abuse may be physical, sexual, or psychological in nature. It is important to emphasize that the majority of children who are encopretic have not been abused (Clayden, 1988). However, in some cases where there has been abuse, the child will soil seemingly as a "cry for help." It is also possible in some cases, where there may be repeated anal rape, for there to be sufficient damage to the anus and musculature in that area that soiling results. This is not a frequent occurrence but is possible. It is important for the clinician to be alert to the possibility of child abuse in cases of encopresis, but it is equally important for the clinician to realize that abuse in these cases is definitely the exception, not the rule.

5.22.3.6.2 Treatment formulation

As noted in the previous section, there appear to be three basic types of conditions that result in soiling (Walker, 1978). One is the manipulative soiler who is using the soiling as an effort to manipulate the environment. This type of case would require a formulation involving family structure and dynamics.

The second category is the child who responds to stress with incontinence. Formulation in these instances will involve an assessment of the internal and external stressors that the child is experiencing in order to plan behavioral as well as other forms of psychotherapy to reduce stress, improve coping, and promote insight or self understanding. Environmental changes may also be required to reduce sources of stress. The overall formulation in these cases will include attempts to improve coping skills of the patient and to simultaneously reduce external stressors such that the problem will be resolved.

The most common etiology for soiling is constipation. The case formulation in these instances involves an evaluation of the factors that led to the constipation and an assessment of the willingness and ability of the child and family to follow the prescribed protocol. The way in which constipation contributes to the problem of encopresis must be understood. There are a number of circumstances through which a child can become constipated. Most of these have to do with diet and toileting behavior. For example, a diet that is lacking in roughage and/or that contains significant amounts of dairy products tends to lead to constipation. Likewise, withholding stools (which children at play often do when they do not wish to interrupt their play) can lead to encopresis. In addition, some individuals appear to have a physiological tendency to become constipated more easily than others. This is probably genetic in origin. There is some suggestion in the literature that certain emotional reactions such as depression may reduce motility of the intestine and eventually produce constipation. The amount of liquid consumed and the amount of dehydration that children experience while playing in warm weather may also be a factor. Lack of exercise is known to be associated with constipation. A number of other factors might also be mentioned, but the main point is that there can be many reasons for the child to become constipated. Unfortunately, when the child becomes constipated, this is frequently not observed by either the child or the parent. The child simply does not take notice of it and the parent assumes that the child has used the toilet at some time when they were not around. Whereas wetting accidents are readily observable, constipation in the early stages is not. Eventually the constipation becomes chronic and results in severe impaction in the colon. This severe impaction and chronic constipation result in stretching the colon which is referred to as psychogenic megacolon. When the colon is stretched and impacted, it ceases to function normally. The peristalic movement that moves material through the intestine and expels it through the anus is muted and unable to perform the task of evacuating the bowel. With this impaction, there is chronic pressure on the anus which results in a loss of the sensation that the child needs to evacuate. Thus, these children frequently report that they do not have the urge to evacuate. Another consequence of chronic impaction is that the liquid material in the intestine that has been emptied from the stomach makes its way only to the point of impaction and is not able to proceed further. As a result, it remains there in a pool. As the child plays or moves around, the wall of the intestine is momentarily separated from the impacted feces allowing a small space through which the liquid material in the pool seeps gradually around the impacted mass and eventually leaks out the anus. This results in the staining of underwear that is very common with encopretic children and which they claim not to be able to predict.

Encopretic children are correct when they say that they did not know it was happening until it was too late, because there was no sensation of contraction and evacuation. The seepage is a passive process. Material simply leaks out the anus without the child having any warning or control over it. In addition to the staining, large bowel movements occur in the clothing or in the toilet when significant amounts of the impacted material are expelled under pressure. These can be extremely embarrassing and upsetting to a child when they happen in public, and at home they are occasionally even large enough that the plumbing facilities cannot accommodate the diameter of the stools. When this happens stools have to be broken into smaller pieces in order to be flushed down the toilet.

These facts are a major part of the formulation and should be communicated to the parents. That is, they should be made aware of the fact that the child has an enlarged colon which is simply not functioning properly and cannot be controlled in the normal way. They should further be informed that the child has lost the sensation of needing to defecate and that the seepage and staining that occurs happens without warning to the child because it is a passive process. Explaining this to the parents often reduces their anger and their disgust because they previously believed that the child was simply defying their authority and refusing to try.

5.22.3.7 Treatment

5.22.3.7.1 Psychosocial treatments

Depending on the formulation of the case, treatment will vary. In cases of manipulative or intentional soiling, the most appropriate treatment would appear to be behavioral psychotherapy to assist the child in coping more effectively with the environment without inappropriate manipulative behavior (Keat, 1979; Walker, Hedberg, Clement, & Wright, 1981). Family therapy may also be very effective in dealing with behavior within the family system that is causing or supporting use of manipulation via soiling (Henggeler & Borduin, 1990).

In cases where diarrhea may be the origin of the soiling, psychotherapy, especially behaviorally oriented psychotherapy, may be helpful in reducing stress and increasing coping skills (Cohen & Reed, 1968; Hedberg, 1973). Anxiety reducing and antidiarrheal medications may also be used (Angelides & Fitzgerald, 1981).

Since the majority of cases of encopresis are based on constipation, the remainder of the remarks in this section are devoted to treatment of this form of encopresis. There have been occasional reports of the treatment of such children with traditional psychotherapy (McTaggert & Scott, 1959; Pinkerton, 1958) as well as family therapy and related approaches (Knights & Pandey, 1990; Margolies & Gilstein, 1983–1984; Wells & Hinkle, 1990; White, 1984).

Numerous case studies and research reports based on adequate samples have reported on the treatment of encopresis using behavioral strategies (Doleys, 1989; Houts & Abramson, 1990; Liebert & Fischel, 1990). Most of these approaches deal with a combination of behavioral principles based on reinforcement and/or punishment along with dietary changes, toileting skills development, changes in toilet habits, and often use of laxatives or enemas for cleansing the colon (Wright & Walker, 1977). Although there is wide variation in the exact components employed in these treatment approaches, a typical approach might involve cleansing the colon via laxatives on the first day of the treatment program, changing the child's diet to make it high in fiber content, and providing rewards for successful toileting attempts as well as for having clean underwear at the end of the day.

Several reports can be found in the literature on the use of biofeedback for bowel control problems (e.g., Whitehead, 1992). Biofeedback procedures are frequently used to assess the functioning of sphincters in children experiencing problems with encopresis. In addition, biofeedback equipment may be used to train a child in proper control of the muscles employed in elimination. Three components are generally employed in these programs: exercise of external sphincter muscles, training in discrimination of rectal sensations, and training in synchronization of the internal and external sphincter muscles so that proper elimination can occur (Latimer, Campbell, & Kasperski, 1984).

There have been reports of the use of hypnosis in the treatment of encopresis. Most of the reports (Olness, 1976; Tilton, 1980) indicate that suggestions are given to the child about the nature of the activity of the colon and of the child's ability to control the process. Finally, there have been attempts to use acupuncture and related procedures in the treatment of encopresis (An et al., 1986).

5.22.3.7.2 Pharmacological treatments

The typical treatment by physicians for constipation-based encopresis involves a regime in which the bowel is evacuated and thoroughly cleared. This is done through enemas and laxatives. The regime is then continued for a period of weeks or months, following which the laxative is either abruptly ceased or phased out. Most commonly, mineral oil (1–3 teaspoons, 2–3 times a day) is employed as the laxative (Abrahamian & Lloyd-Still 1984; Behrman, Vaughan, & Nelson, 1987; Levine, Carey, Crocker, & Gross, 1983). The rationale for this treatment is that the severe impaction has produced psychogenic megacolon, thus compromising the functioning of the colon. Treatment begins with a thorough evacuation of the bowel which is generally readily accomplished by laxatives and enemas; however, there have been occasions when impacted material had to be manually removed prior to beginning treatment. Next, daily use of mineral oil as a laxative produces regularity of bowel movements and produces stools that are easily passed. Maintaining a clear colon over a period of time allows the colon to shrink back to its normal shape, re-establish muscle tone, and begin more normal peristalic movement. When the laxative regime is removed, regular bowel movements frequently continue.

5.22.3.8 Effectiveness of Treatments

Medical and behavioral treatments are the most effective treatments for encopresis. In most reports it is found that 80% or more of children become continent with medical protocols employing mineral oil or other laxatives (Levine & Bakow, 1976; Sondheimer & Gervaise, 1982). Unfortunately, there is a significant rate of relapse following these treatments. Abrahamian and Lloyd-Still (1984) did a five-year follow-up study of their patients and found that 47% were completely symptom free, while another 36% found it necessary to use laxatives intermittently to control the symptoms.

Stark, Spirito, Lewis, and Hart (1990) found that mineral oil oriented programs were unsuccessful with a substantial number of children, especially those with behavioral problems. Referral to a psychologist for treatment in these cases appears to be warranted (Stark, Owens-Stively, Spirito, Lewis, & Guevremont, 1990).

Behavioral treatments for encopresis have been reported by a large number of people in both case studies and controlled research. Very high success rates have been reported for these programs (Doleys, 1989; Houts & Abramson, 1990; Liebert & Fischel, 1990; Walker, 1995).

Although follow-up studies have not been as frequent or as extensive as might be wished, the behaviorally oriented programs do not seem to have as bad a record of relapse as do those based solely on mineral oil or laxatives. The difference may be the greater emphasis on skills development in terms of bowel control, toilet habits, and related areas that are included in the behaviorally oriented programs. Most of the behaviorally oriented programs include laxatives and dietary manipulation, but add a significant dimension of behavioral psychotherapy and habit change.

Biofeedback training is sometimes helpful in bowel training and remediation of encopresis. It is particularly helpful in cases where an organic problem underlies the difficulty or in cases where simple behavioral programs are not effective due to underlying organic or physiological impairments (Whitehead, 1992). For example, biofeedback training has been found to be effective with patients following rectal surgery that impaired the functioning of the anal sphincters. It does not appear to improve success rates in the more routine and uncomplicated cases, however (Loening-Baucke, 1995).

Although there have been intriguing reports about the effectiveness of hypnosis and family therapy in the treatment of encopresis, there is not sufficient data to indicate that these are likely to be successful as a primary or singular treatment for the disorder. They would appear to be effective as adjuncts to an overall treatment program involving laxatives, diet manipulation, and careful toilet training. The same could be said for traditional psychotherapy (Achenbach & Lewis, 1971; Berg & Jones, 1964). Evidence for acupuncture and other related approaches is simply not sufficient to determine whether they are effective or not. It is, however, unlikely that they are.

5.22.3.9 Future Directions for Research and Practice

Walker (1995) proposed a research agenda for encopresis. He noted that, compared to enuresis, relatively little research is done on encopresis. Thus, there is a need for more information on virtually every point regarding encopresis. There is a need for considerably more research on the effects of diet and different foods on the process of digestion and elimination. For example, are there foods that are likely to produce constipation other than dairy products? Additionally, are there foods that promote regularity beyond the simple effects of fiber content?

The information on encopresis related to deliberate or manipulative soiling is very limited. Given the nature of this problem, it is difficult to get a group of patients together at one time for study. However, single case study methods and small group studies can be done and there is a need for considerably more work regarding children with encopresis of this sort. Likewise, whereas there is a considerable amount of information about the effects of stress producing diarrhea, there is relatively little known about precise treatments for this.

Areas involving associated features of encopresis need much more delineation, such as socioeconomic factors, ethnic factors, possible genetic influences, emotional status, and family status of encopretic children. None of these are well understood and better understanding might prove valuable in terms of planning treatment.

Wide variability in the size, composition, odor, and color of stools produced by encopretic as well as normal children have been noted. More information about the relationship between these variables and the function of the colon would be valuable.

With respect to various programs that have successfully employed a combination of laxatives, enemas, diet manipulation, and behavioral training, there has been very little research on the importance of the different components in the package and of possible variations in the components based on presenting symptoms, developmental age, or other factors related to the child.

There are a number of cases, that every clinician in this area has encountered, that seem to be resistant to all efforts employed by a variety of professionals. Careful study of some of these cases on an inpatient basis might reveal the source of the recalcitrance.

Finally, there are a number of related problems to encopresis that have little or no research to date, such as smearing of faces, coprophagia, and coprophilia.

Increased sophistication in treatment protocols can be accomplished only as more data are accumulated in the areas outlined above. Were more information available, it should readily be possible to treat children in a shorter amount of time, with fewer relapses and fewer failures.

5.22.4 SUMMARY

Toilet training is an area of great interest and concern to parents. Parents often regard the development of bowel and bladder control in their children as an important developmental milestone for the child and an affirmation of the parents' competence. Unfortunately, more emphasis is often placed on this process than is warranted. Experts generally recommend assessing the readiness of the child for toilet training and then employing a gentle and patient approach based on encouragement and support. Beginning the process at too early an age and employing excessively harsh approaches can often be harmful to the child.

Failure to achieve proper control of the process of urination is referred to as enuresis. Failure in bowel control is termed encopresis. Both enuresis and encopresis are, by definition, functional disorders of incontinence. Thus, organic bases such as specific disease processes must be ruled out prior to a diagnosis of enuresis or encopresis. A variety of biological and emotional factors have been proposed as causitive or contributing factors to the development of enuresis. However, the disorder can best be understood within the framework of learning theory. Development of urinary continence is a process that involves learning to inhibit reflexive emptying of the bladder, and of emptying the bladder at the appropriate time and place. Biological and emotional factors may inhibit the learning process or interfere with performance of skills already learned; however, they are best regarded as contributory factors. The most successful treatments are use of the pad-and-bell (which appears to be effective due to conditioning) and a variety of package programs which employ the pad-and-bell along with other learning and training experiences for the child. Psychotherapy and a variety of other approaches to the treatment of enuresis have not proved sufficiently successful to be regarded as useful. Medication is successful in some cases but has not been demonstrated to be as effective as learning approaches to the treatment of enuresis and suffers from the problem of side effects as well as the ongoing expense of the treatment.

Although numerous biological and emotional factors have been suggested as causes of encopresis, the most common cause is related to constipation and the resultant psychogenic megacolon. Effective treatment requires thorough evacuation of the bowel which permits the tissue to return to its normal shape, tone, and function. Along with restoration of normal functioning of the tissue, retraining of toilet functions is required. Numerous protocols are in the literature both in the pediatric medical literature and in the psychological literature which describe treatment for encopresis. These involve the use of laxatives or enemas for evacuation of the colon, dietary changes to enhance bowel function, and retraining of toileting skills. These programs have been found to be highly effective. Psychotherapy and other forms of treatment are generally ineffective for treatment of encopresis.

5.23.1 INTRODUCTION

Although eating disorders have been recognized as part of psychiatric nomenclature for many years, it has only been in since the mid-1980s that they have commanded interest in mainstream psychology. Undoubtedly, among the factors responsible for the growing attention shown by researchers and clinicians alike is that eating disorders provide a prototypic model of the complex interaction between cultural, somatic, and psychological factors in the expression of disturbed functioning. The varied psychological features associated with eating disorders contribute to their heterogeneity on presentation. Finally, potentially serious physical and psychological sequelae must be addressed in the understanding and the treatment of the eating disorders. These factors, as well as the apparent increasing prevalence of eating disorders among adolescent and young adult women, have led to a rapid acceleration in theoretical formulations and research bearing on pathogenesis and treatment. Since the mid-1970s there has been divergence in etiological formulations as well as convergence of opinion regarding the utility of certain practical intervention principles. In spite of these advancements, current knowledge has yet to yield conclusive support for any one theoretical viewpoint or treatment modality.

The aims of this chapter are to review diagnostic features, some of the more popular models for understanding eating disorders, and to provide an overview of the major approaches to treatment that derive from different theoretical models.

5.23.2 DIAGNOSTIC AND DEFINING FEATURES

5.23.2.1 Phenomonology

A key feature of anorexia nervosa and bulimia nervosa is a persistent overconcern with body size and shape indicated by behavior such as prolonged fasting, strenuous exercise, and self-induced vomiting aimed at decreasing body weight and fat. In anorexia nervosa, the over-concern has been described variously as a relentless pursuit of thinness (Bruch, 1973), a morbid fear of fatness (Russell, 1970), and a weight phobia (Crisp, 1970). The term “bulimia nervosa” was proposed by Russell (1979) to define a syndrome in which the patient suffers from powerful and intractable urges to overeat leading to bouts of binge eating followed by extreme efforts to control weight through self-induced vomiting, laxative abuse, fasting, vigorous exercise, and other behaviors with similar intent. Bulimia nervosa shares many features in common with anorexia nervosa, however, the patient is not emaciated.

There is general agreement that eating disorder symptoms have psychological and developmental significance. Both individual and family theorists have emphasized that eating disorders often represent a developmental struggle for autonomy, independence, and individuality. These normal development hurdles become flashpoints in adolescence, when the vulnerable individual, parents, or entire family are forced to deal with emergent developmental realities. However, the phenomonology of eating disorders cannot be fully appreciated outside the context of cultural values. There has been intense pressure on women to diet in order to conform to ultra-slender role models for feminine beauty (Garner, 1997; Garner & Garfinkel, 1980). Unfortunately, very few women will ever achieve the admired physical form through restrictive dieting, largely owing to biological limits to achieving permanent weight loss. Nevertheless, constructs such as competence, control, attractiveness, self-worth, and self-discipline have continued to be associated with dieting and weight control in our culture. The consequence of the conflict between cultural imperatives and biological realities has been widespread dissatisfaction with body shape and weight that has even affected young girls yet to cross the pubertal threshold (Edlund, Halvarsson, & Sjödén, 1995).

Another aspect of the phenomonology of anorexia nervosa is the "ego-syntonic" nature of certain symptoms such as pathological dieting and other extreme weight controlling behaviors. In contrast to patients with other psychological disorders such as depression or anxiety, most anorexia nervosa patients actively embrace their eating disorder symptoms. It is not uncommon for patients to actually strive for and then cling to an "anorexic identity" due to the disorder's associations with celebrity status and socially desirable traits. The resistance to change seen in anorexia nervosa has obvious implications for treatment and has been a major focus of therapeutic strategies recommended for this disorder (Garner, Vitousek, & Pike, 1997).

5.23.2.2 Diagnosis

The prevailing diagnostic systems, the *Diagnostic and statistical manual of mental disorders, fourth edition* (*DSM-IV*; American Psychiatric Association [APA], 1994) and the *International Classification of Diseases, 10th revision* (World Health Organization, 1992), formally define as well as distinguish the two major eating disorders, anorexia nervosa and bulimia nervosa. By drawing the boundaries for these eating disorders, the current *DSM-IV* diagnostic criteria have substantial implications for clinical care and research.

5.23.2.2.1 Anorexia nervosa

The requirements for diagnosis of anorexia nervosa according to the *DSM-IV* are summarized as follows: (i) refusal to maintain a body weight over a minimally normal weight for age and height (e.g., weight loss leading to maintenance of a body weight less than 85% of that expected or failure to make expected weight gain during a period of growth); (ii) intense fear of gaining weight or becoming fat, even though underweight; (iii) disturbance in the way that body weight, size, or shape is experienced; (iv) amenorrhea in females (absence of at least three consecutive menstrual cycles).

The *DSM-IV* divides anorexia nervosa into two diagnostic subtypes: (i) restricting type and (ii) binge eating/purging type. The restricting type is defined by rigid restriction of food intake without bingeing or purging, whereas the binge eating/purging type is defined by stringent attempts to limit intake punctuated by episodes of binge eating as well as self-induced vomiting and/or laxative abuse. This diverges from earlier conventions in which anorexia nervosa was subdivided simply on the basis of the presence or absence of binge eating (Casper, Eckert, Halmi, Goldberg, & Davis, 1980; Garfinkel, Moldofsky, & Garner, 1980). Patients who regularly engage in bulimic episodes report greater impulsivity, social/sexual dysfunction, substance abuse, general impulse control problems, family dysfunction, and depression as part of a general picture of more conspicuous emotional disturbance compared to patients with the restricting subtype of anorexia nervosa (Garner, Garfinkel, & O'Shaughnessy, 1985; Garner, Garner, & Rosen, 1993; Herzog, Keller, Sacks, Yeh, & Lavori, 1992; Laessle, Wittchen, Fichter, & Pirke, 1989; Rosen, Murkofsky, Steckler, & Skolnick, 1989). In contrast, restricting anorexia nervosa patients have been described as overly compliant but at the same time obstinate, perfectionistic, obsessive-compulsive, shy, introverted, interpersonally sensitive, and stoical (Casper, 1990, Hsu, Kaye, & Weltzin, 1993; Strober, 1983).

5.23.2.2.2 Bulimia nervosa

The criteria for the diagnosis of bulimia nervosa according to the *DSM-IV* are summarized as follows: (i) recurrent episodes of binge eating (a sense of lack of control over eating a large amount of food in a discrete period of time); (ii) recurrent inappropriate compensatory behavior in order to prevent weight gain (i.e., vomiting, abuse of laxatives, diuretics or other medications, fasting or excessive exercise); (iii) a minimum average of two episodes of binge eating and inappropriate compensatory behaviors per week for the past three months; (iv) self-evaluation unduly influenced by body shape and weight; and (v) the disturbance does not occur exclusively during episodes of anorexia nervosa. Bulimia nervosa patients are further subdivided into purging and nonpurging types based on the regular use of self-induced vomiting, laxatives, or diuretics (APA, 1994).

5.23.2.2.3 *Eating disorders not otherwise specified*

The *DSM-IV* delineates a large and heterogeneous diagnostic category, "eating disorder, not otherwise specified" (EDNOS), for individuals with clinically significant eating disorders but who fail to meet all of the diagnostic criteria for anorexia nervosa or bulimia nervosa. Unfortunately, the term "not otherwise specified" could be interpreted as connoting eating problems of minor clinical significance. This assumption is incorrect since the clinical picture for many individuals with EDNOS can be every bit as complicated and serious as the two main eating disorders (Walsh & Garner, 1997). The binge eating disorder is a specific example of an EDNOS included in the current *DSM-IV*. This term applies to individuals who share a number of characteristics of individuals with bulimia nervosa, but who do not regularly engage in the inappropriate compensatory behaviors, such as self-induced vomiting, required for the diagnosis of bulimia nervosa. In order to qualify for this diagnosis, binge eating must occur, on average, at least twice a week for a six-month period. Although there is merit in adopting the binge eating disorder into the diagnostic nomenclature, it is critical to remain aware of the fact that binge eating and associated psychological symptoms, particularly in the obese, may be attributed to standard weight loss treatments (cf. Garner & Wooley, 1991). Other examples of EDNOS have received less attention but are of clear clinical importance. Terms such as "bulimia," "compulsive eating," "normal weight bulimia," often used to describe eating disorders, do not appear in the *DSM-IV*.

5.23.2.2.4 *Relationship between different eating disorders*

There is extraordinary variability within each of the diagnostic subgroups in terms of demographic, clinical, and psychological variables (Welch, Hall, & Renner, 1990). Patients with anorexia nervosa and bulimia nervosa have been observed to move between diagnostic categories at different points in time (Russell, 1979). For example, patients move between the two subtypes of anorexia nervosa (restricting and binge eating/purging types); however, the tendency is for restricters to move toward bulimia (and purging) more often than bulimic anorexics move to an exclusively abstaining mode (Garner et al., 1993; Hsu, 1988; Kreipe, Churchill, & Strauss, 1989).

Even though distinctions between diagnostic subgroups have been emphasized in the research literature, it is important to recognize that the different diagnostic subgroups tend to share many features in common. For example, even though anorexia nervosa patients are differentiated into "restricter" and "binge eating/purging" subtypes, it must be remembered that virtually all eating disorder patients "restrict their food intake," "diet" and probably "fast" for abnormally long periods of time. Some do this in association with binge eating, some with vomiting, and/or purgation, and some with neither of these symptoms. For some this occurs at a statistically "normal" body weight (bulimia nervosa) and for others it occurs well over the body weight norms (e.g., binge-eating disorder). Figure 1 characterizes the relationship between bingeing, purging, and restricting in subgroups of eating disorder patients at different body weights.

5.23.2.2.5 *Differential diagnosis*

Patients without anorexia nervosa, bulimia nervosa, or some variant can superficially resemble patients with an eating disorder diagnosis. Patients with a severe affective disorder can display marked weight loss (due to loss of appetite) or hyperphagia. Schizophrenia can present with an aversion to eating and occasionally binge eating or purging. Vomiting and weight loss also can be associated with what has been described as a conversion disorder (Garfinkel, Kaplan, Garner, & Darby, 1983). A range of physical illnesses producing weight loss (e.g., inflammatory bowel disease, chronic hepatitis, Addison's disease, Crohn's disease, undiagnosis cystic fibrosis, diabetes mellitus, hyperthyroidism, tuberculosis, malignancies, malabsorption diseases, or other wasting diseases) should be ruled out as the primary diagnosis (Powers, 1997).

5.23.3 EPIDEMIOLOGY

5.23.3.1 Incidence and Prevalence

Incidence rates are defined as the number of new cases in the population per year, whereas prevalence rates refers to the actual number of cases in the population at a certain point in time. Prevalence studies have been the most common and have often been conducted on high-risk populations such as college students and athletes. There are serious limitations to estimates of the incidence and prevalence of eating disorders, because most have been derived exclusively from self-report instruments and on samples that may not reflect important

Purging and bingeing are overlaping sets of symptoms that characterize subgroups of patients at different points along the weight spectrum. Anorexia nervosa patients fall below a critical weight threshold (adapted with permission from Garner, Garner, & Rosen, 1993).

demographic differences in base rates. In general, estimates based exclusively on questionnaires yield much higher rates of eating disorders.

Estimates of incidence based on detected cases in primary care practices yielded rates of 8.1 per 100 000 persons per year for anorexia nervosa and 11.5 for bulimia nervosa (Hoek et al., 1995). The most sophisticated prevalence studies using strict diagnostic criteria report rates of about 0.3% for anorexia nervosa and about 1% for bulimia nervosa among young females in the community (Fairburn & Beglin, 1990; Hoek, 1993). This compares to surveys using questionnaires that find that as many as 19% of female students report bulimic symptoms. Prevalence studies of higher risk samples indicate that serious eating disorders occur in as many as 4% of female high school and college students (cf. Fairburn & Beglin, 1990). Suspected cases of clinical eating disorders or subclinical variants are even more common among groups exposed to heightened pressures to diet or maintain a thin shape. Research has confirmed a high incidence of actual or suspected cases among samples of ballet students and professional dancers, wrestlers, swimmers, skaters, and gymnasts (cf. Garner & Rosen, 1991).

5.23.3.2 Gender Considerations

Epidemiological studies have consistently found that eating disorders are more common among women than men; in clinical samples, only 5–10% of patients are men (Hoek et al., 1995). Studies in the USA suggest the incidence of anorexia nervosa among males may be as little as 0.02% per year and the prevalence of current bulimia nervosa in men is between 0.1% and 0.5%. The differences in gender rates for the eating disorders are generally attributed to cultural factors (Garner & Garfinkel, 1980); however, biological and psychodynamic factors may also play a role (Scott, 1986). Eating disorders are less common in men, but when they occur, they have a clinical picture very similar to that observed in women (Andersen, 1990; Olivardia, Pope, Mangweth, & Hudson, 1995).

5.23.3.3 Developmental Considerations

From the earliest descriptions, there has been agreement that anorexia nervosa is a disorder primarily of adolescence and that the core psychopathology often relates to conflicts that emerge with pubertal changes in body shape.

Theander (1996) reviewed the topic of age at onset and concluded that the average age of onset is usually found to be about 17 years of age with about 30% of cases with an onset at 14 years or younger. Selection bias yields younger age at onset in pediatric treatment facilities. Theander (1996) summarizes the distribution of age at onset as follows: (i) there are occasional patients with an early age of onset (7–10 years of age); (ii) the number of cases rises steeply at ages 11 and 12; (iii) most patients develop in the teenage, 13–19; (iv) there is a gradual decline in onset from 20 to 30 years; and (v) there are fewer cases with an onset after 30 years of age. Some have found that age of onset tends to be a bit younger for males than females; however, this point remains controversial (Theander, 1996).

The age of onset of anorexia nervosa is paralleled by data on body dissatisfaction and dieting in nonclinical populations, again supporting developmental vulnerability. Feeling fat and restricting food intake are common among schoolchildren 7–13 years of age (Davies & Furnham, 1986; Edlund et al., 1995; Maloney, McGuire, & Daniels, 1988; Wardle & Beales, 1986). Dieting to lose weight and fear of fatness are common in girls as young as seven years old; these attitudes and behaviors escalate significantly during adolescence, particularly among those at the heavier end of the weight spectrum (Edlund et al.). In a study of 1410 students in grades 9 through 12 (mean age 16.5 years) Timmerman, Wells, and Chen (1990) reported that 2% of the girls and 0.14% of the boys met all of the diagnostic criteria for bulimia nervosa ascertained through an anonymous self-report instrument. Severe dieting because of a fear of fatness has been shown to lead to short-stature syndrome and delayed puberty in a subgroup of young children (Puglifse, Lifshitz, Grad, Fort, & Marks-Katz, 1983). In 1990, 44% of female high school students were trying to lose weight compared to 15% of male students (Serdula et al., 1993). An additional 26% of female students and 15% of male students were trying to keep from gaining more weight. It has been shown that the risk of developing an eating disorder is eight times higher in dieting compared to nondieting 15-year-old girls (Patton, Johnson-Sabine, Wood, Mann, & Wakeling, 1990). Although there are case reports of anorexia nervosa in young children (Fosson, Knibbs, Bryant-Waugh, & Lask; 1987), the consensus is that it is very rare in this age group (Jaffe & Singer, 1989; Lask & Bryant-Waugh, 1997). Similarly, though probably rarely, cases of anorexia nervosa also have been observed at the other end of the age spectrum (Kellett, Trimble, & Thorley, 1976).

5.23.3.4 Have Eating Disorders Changed Over Time?

Anorexia nervosa was once believed to be restricted to the higher socioeconomic classes; however, there is evidence that it has become more common in middle and lower socioeconomic groups (Gowers & McMahon, 1989). According to Russell (1985, 1997), the most dramatic evidence for a transformation in the psychopathology of anorexia nervosa is the increased appearance of binge eating, both in anorexia nervosa and eating disorder patients who are not emaciated. However, the actual extent to which binge eating has become more common in anorexia nervosa is unclear owing to the fact that the symptom may have been identified less reliably in earlier reports (Garner, 1993).

Casper (1983) suggested another shift in the psychopathology of eating disorders over the past several decades whereby "ascetic motives" for weight loss have become less prominent, replaced by the "drive for thinness" as the most common motivational theme. The theme of asceticism was common in early writings on anorexia nervosa (cf. Bell, 1985; Rampling, 1985) and is expressed in the conceptions of dieting as purification, thinness as virtue, and fasting as an act of penitence. Nevertheless, there is a subgroup of eating disordered patients who seem to be motivated by belief in the virtue of oral self-restraint (Garner & Bemis, 1982, 1985; Garner et al., 1997). Evidence suggests that "oral self-restraint" may be part of a more general theme of renunciation of physical gratification (Haimes & Katz, 1988). This is supported by findings that anorexia nervosa patients have elevated scores on the Asceticism subscale of the Eating Disorder Inventory (Garner, 1991), a subscale designed to identify the tendency to seek virtue through the pursuit of spiritual ideals, such as self-discipline, self-denial, self-restraint, self-sacrifice, and control of bodily urges.

5.23.4 COMORBIDITY

Since the earliest descriptions of anorexia nervosa there has been considerable controversy as to whether eating disorders represent discrete psychological entities or are simply manifestations of other illnesses (cf. Beumont, Al-Alami, & Touyz, 1987). Anorexia nervosa and bulimia nervosa each have been considered variants of affective disorder, obsessive-compulsive disorder, or borderline personality disorder. Traits such as hostility, somatization, social maladjustment, physical anhedonia, affective rigidity, interpersonal sensitivity, anxiety, poor self-esteem, external locus of control, and confused sex-role identity have been observed repeatedly in eating disorder patients (Beumont, George, & Smart, 1976; Garfinkel & Garner, 1982; Garner et al., 1993; Johnson & Connors, 1987; Rastam, Gillberg, & Gillberg, 1995; Strober, 1981; Swift & Wonderlich, 1988; Williamson, 1990). Although there is general acceptance that eating disorders are best considered as discrete clinical entities there is growing interest in psychological features that may define meaningful subgroups of eating-disordered patients.

5.23.4.1 Depression

Depression has been described as a common theme in eating disorders, but its precise role is controversial. Pope and Hudson (1988) originally argued that bulimia nervosa is a variant of depression based on evidence that eating disorder patients exhibit: (i) a high prevalence of depression, (ii) a family history of depression, (iii) biological markers of depression, and (iv) a positive response to antidepressant medications. Detractors from this view provide alternative interpretations for these associations and contend that the nature of bulimia nervosa as a variant of depression is "simplistic and theoretically limiting" (Strober & Katz, 1988). Although depression may play an important predisposing role in eating disorders, current evidence fails to support the proposition that eating disorders are simply depressive equivalents (Cooper & Fairburn, 1986; Hinz & Williamson, 1987; Laessle, Kittl, Fichter, Wittchen, & Pirke, 1987; Wilson & Lindholm, 1987). This said, the evidence is overwhelming that depression is one of the most common experiences of those with eating disorders, and to minimize the significance of this experience would be misleading. Moreover, bulimia nervosa patients with a history of affective disorder or substance abuse disorder report significantly more suicide attempts, social impairment, and previous treatment, both before and after the onset of the eating disorder (Hatsukami, Mitchell, Eckert, & Pyle, 1986). Hatsukami et al. (1986) found no suicide attempts among the group of patients with bulimia alone; however, 26.5% of those with concurrent affective disorder and 32.4% with substance abuse had attempted suicide. Bulimia nervosa patients with a history of substance abuse also report a high incidence of stealing, perhaps suggesting a more general problem with impulsivity.

Some studies indicate that depressive states of varying intensities foreshadow the development of anorexia nervosa with lifetime prevalence rates of major depressive illness ranging between 25% and 80% across different samples (Herzog, Keller, Sacks, Yeh, & Lavori, 1992). Halmi et al. (1991) found a lifetime prevalence of 68% for major depression in a sample of severely ill anorexia nervosa patients. Depression can be secondary to starvation and coexisting complications since improved mood often follows nutritional rehabilitation (Eckert, Halmi, Marchi, & Cohen, 1987). One population study found that depression typically did not precede the eating disorder, although it did correlate with onset (Rastam, 1992). In a six-year follow-up, Rastam et al. (1995) found that affective disorders were common throughout the follow-up period, but tended to follow the course of the disorder rather than to precede or postdate it. Thus, a history of affective disorder may be a foreboding complication for a subgroup of eating-disordered patients who may be particularly resistant to treatment efforts. Unfortunately, this subgroup of patients does not seem to respond more favorably to antidepressant therapy than those without a history of mood disorder (Brotman, Herzog, & Woods, 1984).

5.23.4.2 Anxiety

A lifetime prevalence of social phobia has been identified in more than 25% of anorexia nervosa patients (Halmi et al., 1991). The most common anxiety symptoms documented in anorexia nervosa are obsessive-compulsive (OC) in nature (Halmi et al., 1991; Rastam, 1992; Rastam et al., 1995; Rottenberg, 1988; Thiel, Broocks, Ohlmeier, Jacoby, & Schuβler, 1995). In reviewing comorbidity in anorexia nervosa, Rothenberg (1988) found OC symptoms reported in anywhere between 11% and 83% of patient samples, either during the active phase of the disorder or after weight restoration. In a sample of 93 women with either anorexia or bulimia nervosa, Thiel et al. (1995) found that 37% met diagnostic criteria for OC disorder. These patients with concomitant OC disorder also had higher mean scores on five of eight Eating Disorder Inventory subscale scores. Rastam et al. followed a sample of anorexia nervosa patients six years after onset and found a high rate of OC disorder and that underlying personality disorders tended to predict poor outcome. A common diathesis between eating disorders and OC disorder is suggested by the finding that 11% of 151 women presenting with OC disorder had a history of anorexia nervosa (Kasvikis, Isakiris, Marks, Basoglu, & Noshirvani, 1986).

5.23.4.3 Personality Disorders

Since the mid-1980s, there has been intense interest in the relationship between eating disorders and personality disorders. A number of reports have indicated that almost two-thirds of eating-disordered patients receive a concurrent diagnosis of a personality disorder, with borderline personality disorder being reported as particularly common (Bulik, Sullivan, Joyce, & Carter, 1995; Cooper et al., 1988; Gillberg, Rastam, & Gillberg, 1995; Johnson, Tobin, & Dennis, 1990; Levin & Hyler, 1986; Piran, Lerner, Garfinkel, Kennedy, & Brouilette, 1988). Levin and Hyler (1986) assessed 24 bulimia nervosa patients and found that 15 (63%) met diagnostic criteria for personality disorder, with six (25%) fulfilling the diagnosis for borderline personality disorder. Similarly, Bulik et al. (1995) found at least one personality disorder in 63% of a sample of 76 women with bulimia nervosa. Fifty-one percent of the personality disorders were in cluster C (specifically, avoidant, OC, or dependent personality disorders), 41% in cluster B (particularly, borderline or histrionic), and 33% in cluster A (paranoid, schizoid, or schizotypal). In an earlier evaluation of 35 patients with eating disorders, Gartner, Marcus, Halmi, and Loranger (1989) found that 57% met the *DSM-III-R* diagnostic criteria for at least one form of personality disorder, with borderline, self-defeating, and avoidant being the most common. Two or more Axis II diagnostic criteria were met by 40% of the patients, and 17% fulfilled all of the criteria for 5–7 personality disorder diagnoses. Wonderlich, Swift, Slotnick, and Goodman (1990) interviewed 46 eating-disordered patients and reported that 72% met criteria for at least one personality disorder. OC personality disorder was common among restricting anorexic patients. Histrionic and borderline personality disorder diagnoses were common among bulimic groups. Johnson et al. (1990) followed patients one year after an initial assessment and found that those who initially scored above a threshold on the self-report Borderline Syndrome Index had a worse prognosis in terms of eating behavior and general psychiatric symptoms. Gillberg et al. (1995) found that OC and avoidant personality disorders were particularly common in a study comparing 51 anorexia nervosa patients with an age-matched community sample.

Arguing that borderline assessment measures are confounded by certain eating symptoms, Pope and Hudson (1989) have challenged the interpretation that borderline personality disorder is over-represented among eating disorders. For example, bulimic eating patterns may be used to satisfy the *DSM-III-R* poor impulse control criterion for borderline personality disorder, making the association between disorders tautological. Nevertheless, the tendency toward poor impulse regulation has been identified as a negative prognostic sign in eating disorders (e.g., Hatsukami et al., 1986; Sohlberg, Norring, Holmgren, & Rosmark, 1989). Results from research on the incidence and prevalence of personality disorders in anorexia nervosa are inconsistent. Some studies indicate remarkably high rates, with avoidant personality disorder occurring in as many as 33% of anorexic restricters and borderline personality disorder occurring in almost 40% of anorexic bulimic patients (Piran et al., 1988). Other studies suggest that personality disorders are relatively uncommon in anorexia nervosa (Herzog et al., 1992; Pope & Hudson, 1989). Impulse control problems, such as self-mutilation, suicide attempts, and stealing, are reported in a subgroup of anorexia nervosa patients, particularly those with purging and/or bulimic symptoms (Fahy & Eisler, 1993; Garner et al., 1993). While personality disturbances are not uniform in eating disorders, their presence suggests meaningful subtypes that may be relevant to treatment planning and prognosis.
